Abstract

Chloroplast (cp) DNA is compacted into cpDNA-protein complexes, called cp nucleoids. An abundant and extensively studied component of cp nucleoids is the bifunctional protein sulfite reductase (SiR). The preconceived role of SiR as the core cp nucleoid protein, however, is becoming less likely because of the recent findings that SiRs do not associate with cp nucleoids in some plant species, such as Zea mays and Arabidopsis thaliana. To address this discrepancy, we have performed a detailed phylogenetic analysis of SiRs, which shows that cp nucleoid-type SiRs share conserved C-terminally encoded peptides (CEPs). The CEPs are likely to form a bacterial ribbon–helix–helix DNA-binding motif, implying a potential role in attaching SiRs onto cp nucleoids. A proof-of-concept experiment was conducted by fusing the nonnucleoid-type SiR from Arabidopsis thaliana (AtSiR) with the CEP from the cp nucleoid-type SiR of Phaseolus vulgaris. The addition of the CEP drastically altered the intra-cp localization of AtSiR to cp nucleoids. Our analysis supports the possible functions of CEPs in determining the localization of SiRs to cp nucleoids and illuminates a possible evolutionary scenario for SiR as a cp nucleoid protein.

Key words: nucleoid, sulfite reductase, evolution.

Introduction

Plants originated from a eukaryotic ancestor that integrated a once free-living photosynthetic prokaryote closely related to present-day cyanobacteria, which led to the emergence of chloroplasts (cps; plastids) (Gray 1992; Timmis et al. 2004; Bowman et al. 2007; Bogorad 2008; Keeling 2010). Over time, a drastic transfer of genetic materials from the endosymbiont cyanobacteria (ancestral cps) to the eukaryotic host genome occurred. Consequently, only approximately 120–200 genes are encoded in cps (<10% of full-fledged cyanobacteria) (Timmis et al. 2004), although cpDNA and cp-encoded genes remain critical for photosynthesis, gene expression, and cp biogenesis (Allen 2003; Timmis et al. 2004; Stern et al. 2010).

cpDNA is packaged into cpDNA-protein complexes, called cp nucleoids (Kuroiwa 1991; Sakai et al. 2004; Pfalz and Pfannschmidt 2013, 2015; Powikrowska et al. 2014). Cp nucleoids can be visualized as dot-like structures in cps by staining with DNA-specific fluorochromes such as 4,6-diamidino-2-phenylindole (DAPI) or SYBR Green I, and are ubiquitously observed in diverse taxa of plants and algae. Cp nucleoids are thought to be the functional unit of cpDNA replication, inheritance, and transcription (Kuroiwa 1991; Sakai et al. 2004; Pfalz and Pfannschmidt 2013, 2015; Powikrowska et al. 2014).

Several biochemical and proteomic analyses have revealed the composition of core cp nucleoid proteins (Yagi and Shiina 2012; Timmis et al. 2004; Bowman et al. 2007; Bogorad 2008; Keeling 2010). Over time, a drastic transfer of genetic materials from the endosymbiont cyanobacteria (ancestral cps) to the eukaryotic host genome occurred. Consequently, only approximately 120–200 genes are encoded in cps (<10% of full-fledged cyanobacteria) (Timmis et al. 2004), although cpDNA and cp-encoded genes remain critical for photosynthesis, gene expression, and cp biogenesis (Allen 2003; Timmis et al. 2004; Stern et al. 2010).

cpDNA is packaged into cpDNA-protein complexes, called cp nucleoids (Kuroiwa 1991; Sakai et al. 2004; Pfalz and Pfannschmidt 2013, 2015; Powikrowska et al. 2014). Cp nucleoids can be visualized as dot-like structures in cps by staining with DNA-specific fluorochromes such as 4,6-diamidino-2-phenylindole (DAPI) or SYBR Green I, and are ubiquitously observed in diverse taxa of plants and algae. Cp nucleoids are thought to be the functional unit of cpDNA replication, inheritance, and transcription (Kuroiwa 1991; Sakai et al. 2004; Pfalz and Pfannschmidt 2013, 2015; Powikrowska et al. 2014).

Several biochemical and proteomic analyses have revealed the composition of core cp nucleoid proteins (Yagi and Shiina 2012; Pfalz and Pfannschmidt 2013; Powikrowska et al. 2014). Thus far, bacterial histone-like proteins (Kobayashi et al. 2002; Karcher et al. 2009) and cp nucleoid SAP domain proteins (Kobayashi et al. 2016) have been reported as abundant components in cp nucleoids in unicellular algae. In land plants, various core cp nucleoid proteins have been reported, including sulfite reductase (SiR) (Sato et al. 2001; Chi-Ham et al. 2002), Whirly (Krupinska et al. 2014), SAP domain protein (Pfalz et al. 2006; Majeran et al. 2012), and Switch/sucrose nonfermentable complex B-4 (Melsonek et al. 2012), whereas the histone-like protein gene has not been identified in any of the sequenced genomes. The different compositions of the cp nucleoid proteins could be attributed to cp nucleoid alterations during plant evolution, when the original prokaryotic components were lost or replaced by eu- karyotic proteins (Kobayashi et al. 2016).

Among the cp nucleoid proteins, SiR was the first identified and has been extensively analyzed. SiR was identified as a
major component of the isolated cp nucleoids in soybean (Glycine max) (Cannon et al. 1999; Chi-Ham et al. 2002) and pea (Pisum sativum) (Sato et al. 1997, 2001), and it has the ability to compact DNA, and suppress DNA replication and transcription in vitro (Cannon et al. 1999; Sato et al. 2001; Sekine et al. 2007). SiR is a key enzyme for sulfur assimilation, catalyzing the reduction of sulfite to hydrogen sulfide and water using electrons via ferredoxins. In addition, recent studies indicated that SiR protects leaves against the toxicity of sulfite accumulation and prevents premature senescence caused by a greater sulfite accumulation (Yarmolinsky et al. 2013, 2014).

BLAST-based ortholog searches indicated that the amino acid sequence of SiR is highly conserved among virtually all plant species. Indeed, SiR was also identified in the cp nucleoids of a moss (Physcomitrella patens) (Wiedemann et al. 2010) and tobacco (Nicotiana tabacum) (Jeong et al. 2003). However, a growing number of reports have indicated that the SiR localization patterns are different among plant species. SiR was not identified in the cp nucleoids of Zea mays (Sekine et al. 2007; Majeran et al. 2012) or in the transcriptionally active chromosomes purified from Arabidopsis thaliana and mustard (Pfalz et al. 2006). Based on these reports, the previous assumption that SiR was a universal core cp nucleoid protein in land plants was an oversimplification.

To address this discrepancy, we phylogenetically analyzed SiR. A multiple sequence alignment analysis revealed that catalytic domains of SiRs are highly conserved, except for the C-terminal region. We found that nucleoid-type SiRs have conserved C-terminally encoded peptides (CEPs). The CEP in SiR was predicted to form a bacterial Ribbon–Helix–Helix DNA-binding motif and was not detected in the nonnucleoid-type SiR sites in cp nucleoids (Pfalz et al. 2006). Our analysis indicated the importance of the CEP in determining the localization of SiR to cp nucleoids. We conducted an experiment to test our hypothesis by engineering A. thaliana SiR (AtSiR), which has been reported to localize to the stroma, free from cp nucleoids (Pfalz et al. 2006). Our analysis indicated the importance of the CEP in determining the localization of SiR to cp nucleoids and shed light on a possible evolutionary scenario for SiR as a cp nucleoid protein.

Materials and Methods

Multiple Sequence and Phylogenetic Analyses

SiR homologs were collected from searches using the BLAST algorithm against public databases. The sequences were aligned using ClustalW in MEGA 5.0 (Tamura et al. 2011). The full lengths of the SiR homologs were used for the phylogenetic analyses. Maximum parsimony- and maximum likelihood-based phylogenetic trees were constructed by MEGA 5.0 (Tamura et al. 2011). A Bayesian inference was performed using MrBayes version 3.2 (Ronquist et al. 2012). One million generations were completed, and trees were collected every 1,000 generations, after discarding trees corresponding to the first 25% (burn-in), to generate a consensus phylogenetic tree. Bayesian posterior probabilities were estimated as the proportion of trees sampled after burn-in.

Homology Modeling

A homology model of the P. sativum SiR’s CEP was constructed using Swiss Model using an Escherichia coli Transcriptional Repressor COPG/DNA complex homolog (Protein Data Bank: 1801) as the template. All homology model images were produced using UCSF Chimera 1.5.3r.

Vector Construction

Polymerase chain reaction (PCR) was performed using the proof-reading enzyme KOD-FX Neo (Toyobo Life Science, Osaka, Japan). The PCR products were separated using 1.2% agarose gel electrophoresis, and were gel-purified. AtSiR cDNA was amplified by primers 5'-CACCATGTCACTGACGTTCAGC-CCGGC-3' and 5'-TTGAGAAACTCCTTTGTAGT-3'. To generate AtSiR-PvCEP, overlapping PCR was performed. Briefly, PvCEP was amplified using primers 5'-TACATTACAAAGAGGTTTCTCAACCCATACGCCGACCGACCAGTCTTCTTACAG-3' and 5'-TTACACTTTTCTATTGATGGTTG-3'. The PCR products of AtSiR and PvCEP were mixed and amplified using primers 5'-CATCATCGACGTTCAGC-CCGGC-3' and 5'-TACACTTTTCTATTGATGGTTG-3'. The resulting products were cloned into the pENTRY/D-TOPO vector (Thermo Fisher Scientific Inc., Waltham, MA) and transferred into the pGWB41 vector (Nakagawa et al. 2007) using LR clonase (Thermo Fisher Scientific Inc.).

Growth Conditions and Nuclear Transformations

Arabidopsis thaliana (Columbia) was grown in soil in a growth chamber (50 μmol of photons m⁻² s⁻¹, 16-h photoperiod, 23 °C). Nuclear transformation was performed using the Agrobacterium-mediated transformation method.

Microscopic Observations

Confocal laser scanning microscopy of A. thaliana leaves was performed using a Leica TCS SP5 (Leica Microsystems, Wetzlar, Germany). To isolate cps, leaves were disrupted in 0.3 M mannitol medium using a surgical scalpel. Isolated cps were stained with 1 μg/ml DAPI and observed with an epifluorescence/differential interference microscope (BX51; Olympus, Tokyo, Japan) connected to a charge-coupled device camera (DP72; Olympus).

Results and Discussions

Nucleoid-Type SiRs Have Conserved Peptides in Their Termini

To reveal the molecular basis underlying the different localizations of SiRs in cps, their primary structures were compared...

using a multiple alignment analysis. Plant-type SiRs have two nitrite/SiR ferredoxin-like half domains (Pfam: 03460), and two nitrite and SiR 4Fe-4S domains (Pfam: 01077). Our sequence analysis showed that the catalytic domains are highly conserved in all plants, regardless of the localization patterns (fig. 1). However, a conserved short peptide (~50 amino acids) in the C-terminal region was found specifically in the amino acid sequences of cp nucleoid-type SiRs and not in the

nonnucleoid-type SiRs, such as *Z. mays*’ *SiR* and *AtSiR*. The CEP was predicted to form a ribbon–helix–helix structure, a bacterial DNA-binding motif, using the SWISS homology modeling program (Biasini et al. 2014), suggesting that it has a role in attaching SiR onto cp nucleoids (fig. 2).

*AtSiR* was not identified in the transcriptionally active chromosomes purified from *Arabidopsis* and mustard chloroplasts, suggesting that *AtSiR* may not be specifically localized to cp nucleoids (Pfalz et al. 2006). To confirm the actual subcellular localization, a chimeric SiR protein fused with yellow fluorescent protein was expressed under the control of the 35S promoter (*35Sp::AtSiR-YFP*). Although the expression was driven by the constitutive promoter, the *AtSiR-YFP* fluorescence signal was mainly observed in the guard cells of independent stable lines (fig. 3A). This accumulation pattern is partly consistent with the transcriptome data, which indicated a relatively higher SiR expression level in guard cells than in mesophyll cells (Winter et al. 2007; Yang et al. 2008), implying a posttranscriptional regulation of SiR expression. A similar accumulation pattern was reported for the gene encoding ATP sulfurylase, the enzyme that catalyzes the entry step of the sulfate assimilation pathway (Bohrer et al. 2015). Confocal microscopy showed that *AtSiR* was localized uniformly in the chloroplast (fig. 3A). The DAPI staining of isolated cps

**Fig. 4.**—Phylogenetic points at which CEP was lost. A phylogenetic tree of SiRs based on Bayesian inference, maximum likelihood and maximum parsimony methods. Posterior probabilities for Bayesian inference (≥0.90) and Bootstrap values (≥50%) for the maximum likelihood and maximum parsimony, respectively, are indicated at the appropriate nodes. Blue indicates SiRs containing CEPs. Green indicates SiRs not containing CEPs.
showed that AtSiR-YFP is not preferentially colocalized with cp nucleoids, indicating that AtSiR is mainly localized to the stroma (fig. 3B).

We next tested whether the localization of AtSiR can be changed by the addition of CEP in cps. Chimeric AtSiR was fused with the CEP of the SiR from bean (Phaseolus vulgaris) and expressed under the control of the 35S promoter (35Spro::AtSiR-PvSEP-YFP). This chimeric protein was also mainly detected in the guard cells (fig. 3A). However, we found that the AtSiR-PvCEP-YFP fluorescence signals were observed as dot-like structures in cps (fig. 3A). DAPI staining of isolated cps showed that the AtSiR-PvCEP-YFP signal was
precisely co-localized with the cp nucleoids (fig. 38). These results support our hypothesis that the CEP is a critical factor for SiR’s binding to cp nucleoids.

Evolution of SiRs as cp Nucleoid Protein

Bacterial SiR is a large enzyme with an α8β4 quaternary structure. The α-subunits contain both flavin adenine dinucleotide and flavin mononucleotide, whereas the β-subunits contain an iron-sulfur cluster coupled to a siroheme. The α-subunits have diaphorase activity that catalyzes the electron flow from NADPH to sulfite via flavin adenine dinucleotide, flavin mononucleotide and siroheme (Siegel and Davis 1974; Zehgoufi et al. 2000). Plant- and cyanobacteria-type SiRs are homologous to the β-subunits and catalyze the reduction of sulfite using electrons donated from photosystem I via ferredoxin (Krueger and Siegel 1982). A previous biochemical analysis indicated that cyanobacterial SiR, which is thought to be the ancestor of chloroplast SiRs, is not localized to cp nucleoids (Sato et al. 2004).

To deduce the evolution of SiR as a cp nucleoid protein, a phylogenetic analysis was performed. One critical feature missing in nonnucleoid-type SiRs was CEP. CEP is conserved among plant SiRs, except for those in grasses and brassicas that do not colocalize with cp nucleoids (fig. 4), which implies that nonnucleoid-type SiRs in land plants could have been derived from cp nucleoid-type SiRs by the spontaneous loss of CEP. CEP is also detected in cyanobacterial SiRs and red algal SiRs. While the amino acid identities of cyanobacterial and red algal CEPs are relatively low when compared with those of land plants (e.g., the amino identity between Cyanidioschyzon merolae SiR [CmSiR] and PpcCEP is <30%), these CEPs are also likely to form the RHH motif, suggesting that CEP originated from the endosymbiont’s SiR (fig. 4, supplementary figs. S1 and S2, Supplementary Material online). We also found that CmSiR is closely related to cyanobacterial SiRs and distant from the cp nucleoid-type SiRs (fig. 4), which is consistent with CmSiR not localizing to cp nucleoids (Sato et al. 2004). Furthermore, SiRs in flowering plants showed close phylogenetic relationships regardless of the localization patterns (fig. 4). Thus, we propose that the evolution of nucleoid-type SiRs can be divided into three steps: First, ancient plant cells acquired the SiR gene from the endosymbiont cyanobacterium; Second, the SiR accumulated amino acid sequence changes, resulting in a conformational change that allowed the interaction with cp nucleoids prior to the birth of land plants; and finally, some land plants independently lost CEP, which is not essential for catalytic reactions, causing the conformational change that impaired their DNA-binding ability (fig. 5).

The physiological advantages of having SiR as a component of the cp nucleoids remain unclear. Plant SiR, which is regarded as the “bottleneck” in the reductive sulfate metabolic pathway (Khan et al. 2010), plays an important role in protecting leaves against the toxicity of sulfite accumulation. The protective function appears to be especially important in cpss, because severe chlorophyll degradation, the reduction of D1 and psbO proteins, and the deterioration of photosynthesis were observed in SiR-impaired plants (Yarmolinsky et al. 2013, 2014). One possible physiological advantage of the association of SiR with cp nucleoids would be that SiR protects cpDNA from mutagenic bisulfite ion-based modifications (Sato et al. 2001) because cytosine can be converted to uracil by deamination when reacting with bisulfite (Clark et al. 1994). Another possibility is that the nucleoid-localized SiR acts as a sensor for the redox state within cpss to modulate cp gene expression through the regulation of the cp nucleoid structure in response to various environmental conditions and developmental stages (Sekine et al. 2007).

We have not found any visible phenotypic effects caused by the overexpression of the cp nucleoid-type AtSiR-CEP in Arabidopsis thaliana under normal growth conditions. However, the possibility remains that the association of SiR with cp nucleoids may be advantageous or disadvantageous under some conditions. Further analyses, including physiological and biochemical experiments, are necessary to reveal the functions of nucleoid-localized SiRs and why some land plants abandoned cp nucleoid-type SiRs during evolution.
