ABSTRACT

N-Body simulations are an important tool in the study of formation of large scale structures. Much of the progress in understanding the physics of galaxy clustering and comparison with observations would not have been possible without N-Body simulations. Given the importance of this tool, it is essential to understand its limitations as ignoring these can easily lead to interesting but unreliable results. In this paper we study the limitations due to the finite size of the simulation volume. In an earlier work we proposed a formalism for estimating the effects of a finite box-size on physical quantities and applied it to estimate the effect on the amplitude of clustering, mass function. Here, we extend the same analysis and estimate the effect on skewness and kurtosis in the perturbative regime. We also test the analytical predictions from the earlier work as well as those presented in this paper. We find good agreement between the analytical models and simulations for the two point correlation function and skewness. We also discuss the effect of a finite box size on relative velocity statistics and find the effects for these quantities scale in a manner that retains the dependence on the averaged correlation function $\xi$.

Key words: methods: N-Body simulations, numerical – gravitation – cosmology : theory, dark matter, large scale structure of the universe

1 INTRODUCTION

Large scale structures like galaxies and clusters of galaxies are believed to have formed by gravitational amplification of small perturbations. For an overview and original references, see, e.g., Peebles (1980); Peacock (1999); Padmanabhan (2002); Bernardeau et al. (2002). Density perturbations are present at all scales that have been observed (Percival et al. 2007; Komatsu et al. 2008). Understanding the evolution of density perturbations for systems that have fluctuations at all scales is essential for the study of galaxy formation and large scale structures. The equations that describe the evolution of density perturbations in an expanding universe have been known for a long time (Peebles 1974) and these are easy to solve. The equations that describe the evolution of density perturbations for systems that have fluctuations at all scales is essential for the study of galaxy formation and large scale structures. These equations describe the evolution of density contrast defined as $\delta(r, t) = (\rho(r, t) - \bar{\rho}(t))/\bar{\rho}(t)$. Here $\rho(r, t)$ is the density at $r$ at time $t$, and $\bar{\rho}$ is the average density in the universe at that time. These are densities of non-relativistic matter, the component that clusters at all scales and is believed to drive the formation of large scale structures in the universe. Once the density contrast at relevant scales becomes large, i.e., $|\delta| \geq 1$, the perturbation becomes non-linear and coupling with perturbations at other scales cannot be ignored. The equations that describe the evolution of density perturbations cannot be solved for generic perturbations in this regime. The evolution of density perturbations is described by the continuity equation and the equation of state $\rho = \rho(H)$ for the universe.

N-Body simulations (Bertschinger 1998; Bagla and Padmanabhan 1997b; Bagla 2005; Dolag et al. 2008) are often used to study the evolution in this regime. Alternative approaches can be used if one requires only a limited amount of information and in such a case either quasi-linear approximation schemes (Zel’dovich 1970; Little et al. 1991; Bagla & Prasad 2003) or scaling relations (Davis & Peebles 1977; Hamilton et al. 1991; Jain et al. 1995; Kanekar 2000; Ma 1998; Nityananda & Padmanabhan 1994; Padmanabhan et al. 1996; Peacock & Dodds 1994; Padmanabhan 1996; Peacock & Dodds 1996; Smith et al. 2003) suffice.

In cosmological N-Body simulations, we simulate a representative region of the universe. This is a large but finite volume and periodic boundary conditions are often used. Almost always, the simulation volume is taken to be a cube. Effect of perturbations at scales smaller than the mass resolution of the simulation, and of perturbations at scales larger than the box is ignored. Indeed, even perturbations at scales comparable to the box are under sampled.

It has been shown that perturbations at small scales do not influence collapse of perturbations at much larger scales in a significant manner (Peebles 1974, 1985; Little et al. 1991; Bagla & Padmanabhan 1997a; Couchman & Peebles 1998; Bagla & Prasad 2008). This is certainly true if the scales of interest are in the non-linear regime (Bagla & Padmanabhan 1997a; Bagla & Prasad 1997b; Bagla 2005; Dolag et al. 2008) are often used to study the evolution in this regime. Alternative approaches can be used if one requires only a limited amount of information and in such a case either quasi-linear approximation schemes (Zel’dovich 1970; Little et al. 1991; Bagla & Prasad 2003) or scaling relations (Davis & Peebles 1977; Hamilton et al. 1991; Jain et al. 1995; Kanekar 2000; Ma 1998; Nityananda & Padmanabhan 1994; Padmanabhan et al. 1996; Peacock & Dodds 1994; Padmanabhan 1996; Peacock & Dodds 1996; Smith et al. 2003) suffice.
2 Bagla, Prasad and Khandai

Therefore we may assume that ignoring perturbations at scales much smaller than the scales of interest does not affect results of N-Body simulations.

Perturbations at scales larger than the simulation volume can affect the results of N-Body simulations. Use of the periodic boundary conditions implies that the average density in the simulation box is same as the average density in the universe, in other words we ignore perturbations at the scale of the simulation volume (and at larger scales). Therefore the size of the simulation volume should be chosen so that the amplitude of fluctuations at the box scale (and at larger scales) is negligible. If the amplitude of perturbations at larger scales is not negligible then clearly the simulation is not a faithful representation of the model being studied. It is not obvious as to when fluctuations at larger scales can be considered negligible, indeed the answer to this question depends on the physical quantity of interest, the model being studied and the specific length/mass scale of interest as well.

The effect of a finite box size has been studied using N-Body simulations and the conclusions in this regard may be summarised as follows.

- If the amplitude of density perturbations around the box scale is small ($\delta < 1$) but not much smaller than unity, simulations underestimate the correlation function though the number density of small mass haloes does not change by much (Gelb & Bertschinger 1994a,b). In other words, the formation of small haloes is not disturbed but their distribution is affected by non-inclusion of long wave modes.
- In the same situation, the number density of the most massive haloes drops significantly (Gelb & Bertschinger 1994a,b; Bagla & Ray 2005).
- Effects of a finite box size modify values of physical quantities like the correlation function even at scales much smaller than the simulation volume (Bagla & Ray 2005).
- The void spectrum is also affected by finite size of the simulation volume if perturbations at large scales are not ignorable (Kauffmann & Melott 1992).
- It has been shown that properties of a given halo can change significantly as the contribution of perturbations at large scales is removed to the initial conditions but the distribution of most internal properties remain unchanged (Power & Knebe 2006).
- We presented a formalism for estimating the effects of a finite box size in Bagla & Prasad (2006). We used the formalism to estimate the effects on the rms amplitude of fluctuations in density, as well as the two point correlation function. We used these to further estimate the effects on the mass function and the multiplicity function.
- The formalism mentioned above was used to estimate changes in the formation and destruction rates of haloes (Prasad 2007).
- It was pointed out that the second order perturbation theory and corrections arising due this can be used to estimate the effects due to a finite box size (Takahashi et al. 2008). This study focused specifically on the effects on baryon acoustic oscillations.
- If the objects of interest are collapsed haloes that correspond to rare peaks, as in the study of the early phase of reionisation, we require a fairly large simulation volume to construct a representative sample of the universe (Barkana & Loeb 2004; Reed et al. 2008).

In some cases, one may be able to devise a method to “correct” for the effects of a finite box-size (Colombi et al. 1994), but such methods cannot be generalised to all statistical measures or physical quantities.

effects of a finite box size modify values of physical quantities even at scales much smaller than the simulation volume (Bagla & Ray 2005; Bagla & Prasad 2006). A workaround for this problem was suggested in the form of an ensemble of simulations to take the effect of convergence due to long wave modes into account (Sirkko 2005), the effects of shear due to long wave modes are ignored here. However it is not clear whether the approach where an ensemble of simulations is used has significant advantages over using a sufficiently large simulation volume.

We review the basic formalism we proposed in (Bagla &Prasad 2006) in §2. We then extend the original formalism to the cases of non-linear amplitude of clustering and also for estimating changes in skewness and other reduced moments of counts in cells. This is done in §3. In §4 we confront our analytical models with N-Body simulations. We end with a discussion in §5.

2 THE FORMALISM

Initial conditions for N-Body simulations are often taken to be a realisation of a Gaussian random field with a given power spectrum, for details see, e.g., Bagla and Padmanabhan (1997b); Bertschinger (1998); Bagla (2005); Dolag et al. (2008). The power spectrum is sampled at discrete points in the k space between the scales corresponding to the box size (fundamental mode) and the grid size (Nyquist frequency/mode). Here $k$ is the wave vector.

We illustrate our approach using $rms$ fluctuations in mass $\sigma(r)$, but as shown below, the basic approach can be generalised to any other quantity in a straightforward manner. In general, $\sigma(r)$ may be defined as follows:

$$\sigma^2(r) = \int_0^\infty \frac{dk}{k} \frac{k^3 P(k)}{2\pi^2} W^2(kr)$$

(1)

Here $P(k)$ is the power spectrum of density contrast, $r$ is the comoving length scale at which $rms$ fluctuations are defined, $k = \sqrt{k_x^2 + k_y^2 + k_z^2}$ is the wave number and $W(kr)$ is the Fourier transform of the window function used for sampling the density field. The window function may be a Gaussian or a step function in real or k-space. We choose to work with a step function in real space where $W(kr) = 9 (\sin kr - kr \cos kr)^2/(kr)^6$, see e.g., §5.4 of Padmanabhan (1993) for further details. In an N-Body simulation, the power spectrum is sampled only at specified points in the k-space. In this case, we may write $\sigma^2(r)$ as a sum over these points.

$$\sigma^2(r, L_{box}) = \frac{9}{V} \sum_k P(k) \left[ \frac{\sin kr - kr \cos kr}{k^3 r^3} \right]^2$$

$$\approx 2\pi/L_{grid} \int \frac{dk}{k} \frac{k^3 P(k)}{2\pi^2} \left[ \frac{\sin kr - kr \cos kr}{k^3 r^3} \right]^2$$

$$\approx 2\pi/L_{box} \int_0^\infty \frac{dk}{k} \frac{k^3 P(k)}{2\pi^2} \left[ \frac{\sin kr - kr \cos kr}{k^3 r^3} \right]^2$$

$$= \int_0^\infty \frac{dk}{k} \frac{k^3 P(k)}{2\pi^2} \left[ \frac{\sin kr - kr \cos kr}{k^3 r^3} \right]^2$$
Here $\sigma_0^2(r)$ is the expected level of fluctuations in mass at scale $r$ for the given power spectrum and $\sigma^2(r, L_{\text{box}})$ is what we get in an N-Body simulation at early times. We have assumed that we can approximate the sum over the $k$ modes sampled in initial conditions by an integral. Further, we make use of the fact that small scales do not influence large scales to ignore the error contributed by the upper limit of the integral. This approximation is valid as long as the scales of interest are more than a few grid lengths.

In the approach outlined above, the value of $\sigma^2$ at a given scale is expressed as a combination of the expected value $\sigma_0^2$ and the correction due to the finite box size $\sigma^2_{\text{box}}(r)$. Here $\sigma_0^2$ is independent of the box size and depends only on the power spectrum and the scale of interest. It is clear than $\sigma^2(r, L_{\text{box}}) \leq \sigma_0^2(r)$, and, $\sigma^2(r, L_{\text{box}}) \geq 0$. It can also be shown that for hierarchical models, $d\sigma^2(r, L_{\text{box}})/dr \leq 0$, i.e., $\sigma^2(r, L_{\text{box}})$ decreases or saturates to a constant value as we approach small $r$.

At large scales $\sigma_0^2(r)$ and $\sigma^2(r, L_{\text{box}})$ have a similar magnitude and the rms fluctuations in the simulation become negligible compared to the expected values in the model. As we approach small $r$ the correction term $\sigma^2_{\text{box}}(r)$ is constant and for most models it becomes insignificant in comparison with $\sigma_0^2(r)$. In models where $\sigma_0^2(r)$ increases very slowly at small scales or saturates to a constant value, the correction term $\sigma^2_{\text{box}}$ can be significant at all scales.

This formalism can be used to estimate corrections for other estimators of clustering, for example the two point correlation. See Bagla & Prasad (2006) for details.

The estimation of the rms amplitude of density perturbations allows us to use the theory of mass function and estimate a number of quantities of interest. For details, we again refer the reader to Bagla & Prasad (2006) but we list important points here.

- The fraction of mass in collapsed haloes is under-estimated in N-Body simulations. This under-estimation is most severe near the scale of non-linearity, and falls off on either side. If we consider fractional under-estimation in the collapsed fraction then this increases monotonically from small scales to large scales.
- The number density of collapsed haloes is under-estimated at scales larger than the scale of non-linearity. The maximum in collapsed fraction near the scale of non-linearity leads to a change in sign of the effect of a finite box-size for the number density of haloes at this scale: at smaller scales the number density of haloes is over-estimated in simulations. This can be understood on the basis of a paucity of mergers that otherwise would have led to formation of high mass haloes.
- The above conclusions are generic and do not depend on the specific model for mass function. Indeed, expressions for both the Press-Schechter (Press & Schechter 1974) and the Sheth-Tormen (Sheth & Tormen 1999; Sheth, Mo, & Tormen 2001) mass functions are given in Bagla & Prasad (2006), and we have also checked the veracity of our claims for the Jenkins et al. (2001) mass function.

### 3 REDUCED MOMENTS

In this section we outline how the formalism and results outlined above may be used to estimate the effect of a finite box-size on reduced moments. Reduced moments like the skewness and kurtosis can be computed using perturbation theory in the weakly non-linear regime (Bernardeau 1994). The expected values of the reduced moments are related primarily to the slope of the initial or linearly extrapolated $\sigma^2(r)$, as all non-Gaussianities are generated through evolution of the Gaussian initial conditions and the initial $\sigma^2(r)$ characterises this completely. We can use the expression for $\sigma^2(r)$ as it is realised in simulations with a finite box size to compute the expected values of reduced moments in N-Body simulations in the weakly non-linear regime.

$$S_3 = \frac{34}{7} + \frac{\partial \ln \sigma^2}{\partial \ln r} \quad \Rightarrow \quad \frac{34}{7} - \frac{(n+3)}{r} \frac{\partial (\sigma^2/\sigma_0^2)}{\partial \ln r} + \mathcal{O}\left(\frac{\partial \ln (\sigma^2/\sigma_0^2)}{\partial \ln r}\right)^2$$

$$S_4 = \frac{6071}{1323} + 62 \frac{\partial \ln \sigma^2}{\partial \ln r} + 7 \left[ \frac{\partial \ln \sigma^2}{\partial \ln r} \right]^2 + 2 \frac{\partial^2 \ln \sigma^2}{\partial \ln^2 r} \quad \Rightarrow \quad \frac{6071}{1323} - \frac{62}{3} (n+3) \left[ 1 + \frac{\sigma^2}{\sigma_0^2} \right] + \frac{7}{3} (n+3)^2 \left[ 1 - \frac{8 \sigma^2}{7 \sigma_0^2} \right]$$

$S_{3,4}$ is the expected value of $S_{3,4}$ for the given mode, i.e., when there are no box corrections and $S_{3,4}$ is the correction term in $S_{3,4}$ due to a finite box size. Box size effects lead to a change in slope of $\sigma^2$, and hence the effective value of $n$ changes. The last term is the offset in skewness in N-Body simulations as compared with the expected values in the model being simulated. We would like to emphasise that this expression is valid only in the weakly non-linear regime.

In general we expect $\sigma^2/\sigma_0^2$ to increase as we go to larger scales. Thus the skewness is under estimated in N-Body simulations and the level of under estimation depends on the slope of $\sigma^2/\sigma_0^2$ as compared to the slope of $\sigma_0^2$. In the limit of small scales where $\sigma^2$ is almost independent of scale, we find that the correction is:

$$S_3 \approx \frac{34}{7} - \frac{(n+3)}{r} \frac{\partial (\sigma^2/\sigma_0^2)}{\partial \ln r} + \mathcal{O}\left(\frac{\partial \ln (\sigma^2/\sigma_0^2)}{\partial \ln r}\right)^2,$$

$$S_4 \approx \frac{6071}{1323} - \frac{62}{3} (n+3) \left[ 1 + \frac{\sigma^2}{\sigma_0^2} \right] + \frac{7}{3} (n+3)^2 \left[ 1 - \frac{8 \sigma^2}{7 \sigma_0^2} \right].$$
\[ + \mathcal{O} \left( \frac{\partial}{\partial \ln r} \left( \frac{\sigma^2}{\sigma_0^2} \right)^2 \right) + \mathcal{O} \left( \frac{1}{\sigma_0^2} \frac{\partial \sigma^2}{\partial \ln r} \right) \]

4 N-BODY SIMULATIONS

In this section we compare the analytical estimates for finite box size effects for various quantities with N-Body simulations. Such a comparison is relevant in order to test the effectiveness of approximations made in computing the effects of a finite box size. We have made the following approximations:

- Effects of mode coupling between the scales that are taken into account in a simulation and the modes corresponding to scales larger than the simulation box are ignored. We believe that this should not be important unless the initial power spectrum has a sharp feature at scales comparable with the simulation size.

- Sampling of modes comparable to the box size is sparse, and the approximation of the sum over wave modes as an integral can be poor if the relative contribution of these scales to \( \sigma_1 \) is significant.

Table 1 gives details of the N-Body simulations used in this paper. In order to simulate the effects of a finite box size, we used the method employed by Bagla & Ray (2005) where initial perturbations are set to zero for all modes with wave number smaller than a given cutoff \( k_c \). The initial conditions are exactly the same as the reference simulation in each series in all other respects. For a finite box simulation, there is a natural cutoff at the fundamental wave number \( k_f = 2\pi/L_{\text{box}} \) and simulations A1, B1 and C1 impose no other cutoff. These are the reference simulations for the two series of simulations. Simulations A2, B2 and C2 sample perturbations at wave numbers larger than \( 2k_f \) whereas simulations A3, B3 and C3 are more restrictive with non-zero perturbations above \( 4k_f \). The cutoff of \( 2k_f \) and \( 4k_f \) corresponds to scales of 128 and 64 grid lengths, respectively. For the C series of simulations, the cutoff of \( 2k_f \) and \( 4k_f \) corresponds to scales of \( 80 h^{-1}\text{Mpc} \) and \( 40 h^{-1}\text{Mpc} \), respectively.

The background cosmology was taken to be Einstein-deSitter for the A and B series simulations. The best fit \(^{\Lambda}\)CDM model from WMAP-5 (Dunkley et al. 2008) was used for the C series of simulations.

In order to ensure that the initial conditions do not get a rare contribution from a large scale mode, we forced \( |\delta_k|^2 = P(k) \) while keeping the phases random for modes \( k \geq 6k_f \).

We have chosen to work with models where box size effects are likely to be significant, particularly with the larger cutoff in wave number. This has been done to test our analytical model in a severe situation, and also to further illustrate the difficulties in simulating models with large negative indices.

We present results from N-Body simulations in the following section.

4.1 Results

We begin with a visual representation of the simulations. Figure 1 shows a slice from simulations A1, A2 and A3 at two different epochs. The left panel is for the early epoch when \( r_{nl} = 2 \) grid lengths in the model without a cutoff, and the right panel is for \( r_{nl} = 8 \) grid lengths. The top row is for the simulation A1, the middle row is for the simulation A2 and the lowest row is for the simulation A3. The relevance of box size effects is apparent as the evolution of small scale features is not of interest in the present study. Simulations for both the A and the B series were done with the Einstein-deSitter background and the C series used the WMAP-5 best fit (BF) model as the cosmological background, as also for the power spectrum and transfer function.

Table 1. This table lists characteristics of N-Body simulations used in our study. Here the spectral index gives the slope of the initial power spectrum and the cutoff refers to the wave number below which all perturbations are set to zero: \( k_f = 2\pi/L_{\text{box}} \) is the fundamental wave mode for the simulation box. All models were simulated using the TreePM code (Bagla 2002; Bagla & Ray 2003; Khandai & Bagla 2008); \( 256^3 \) particles were used in each simulation, and the PM calculations were done on a \( 256^3 \) grid. Power spectra for both the A and the B series of simulations were normalised to ensure \( \sigma = 1 \) at the scale of 8 grid lengths at the final epoch if there is no box-size cutoff. A softening length of 0.1 grid lengths was used as the evolution of small scale features is not of interest in the present study. Simulations for both the A and the B series were done with the Einstein-deSitter background and the C series used the WMAP-5 best fit (BF) model as the cosmological background, as also for the power spectrum and transfer function.

\[ k_f \]

\[ 2k_f \]

\[ 4k_f \]

\[ 160 h^{-1}\text{Mpc} \]

\( n = -2.5 \). This constraint is even stronger for models with the slope of the power spectrum closer to \( n = -3 \).

Figure 3 shows the visual appearance for the C series of simulations. Once again we find a significant change in appearance even with \( k_c = 2k_f \) at the earlier epoch, \( z = 1 \) in this case. This indicates that a box-size of \( 80 h^{-1}\text{Mpc} \) is insufficient if we wish to achieve convergence in the large scale distribution of matter in models of cosmological interest. This reinforces conclusions of Bagla & Ray (2005) where we found that a box size of around \( 150 h^{-1}\text{Mpc} \) is required for convergence in simulations of \(^{\Lambda}\)CDM models.
Figure 1. The first, second and the third row in this figure show the slices for models A1, A2 and A3 (see table for details) respectively at an early epoch when the scale of nonlinearity is 2 grid lengths (left column) and a later epoch when the scale of nonlinearity is 8 grid lengths (right column).
Figure 2. The first, second and the third row in this figure show the slices for the models B1, B2 and B3 respectively at an early epoch when the scale of nonlinearity is 2 grid lengths (left column) and a later epoch (right column) when the scale of nonlinearity is 8 grid lengths (right column)
Figure 3. The first, second and the third row in this figure show the slices for the $\Lambda$CDM simulations C1, C2 and C3 respectively at an early epoch ($z = 1$) (left column) and the present epoch ($z = 0$) (right column).
Figure 4. The first two rows in this figure show the average two point correlation function \( \bar{\xi} \), and the next two rows show skewness \( S_3 \). The first and third row represent the early epoch and the second and fourth row represent the later epoch respectively. In all the panels models with \( k_c = k_f \), \( k_c = 2k_f \) and \( k_c = 4k_f \) are represented by the solid, dashed and dot-dashed lines respectively. In all the panels, corresponding to every model in simulation (thick lines) theoretical estimates (thin lines) are also shown. Horizontal dashed lines in the lower rows shows the expected value of \( S_3 \) in absence of any box-size corrections for the power law models.
4.2 Clustering Amplitude

The left column in Figure 4 shows the volume averaged correlation function $\bar{\xi}$ for the simulations being studied here. The top-left panel is for simulations A1, A2 & A3 at an early epoch ($r_{nl} = 2$ grid lengths in the model without a cutoff) and the second panel from top in this column shows $\bar{\xi}$ for the same simulations at a late epoch ($r_{nl} = 8$ grid lengths). The corresponding plots in the second column show the same for the simulations in the B series, and the third column is for the C series of simulations. We have shown $\bar{\xi}$ as a function of scale in these panels. Also shown are the linearly extrapolated values of $\bar{\xi}$ computed using our formalism for estimating the effects of a finite box-size. Data from N-Body simulations is shown as thick curves whereas the theoretical estimate is shown as thin curves with the corresponding line style. It is clear that the analytical estimate for $\bar{\xi}$ in a finite box captures the qualitative nature of the change from the expected values. The match is better at large scales where $\bar{\xi}$ is small and this is expected as the analytical estimate is linearly extrapolated whereas we are comparing it with results from an N-Body simulation. Our analysis works better for the $n = -2$ model used in the A series of simulations and for the $\Lambda$CDM model in the C series of simulations as compared to the B series of simulations for the $n = -2.5$ model where it systematically under-estimates the suppression of $\bar{\xi}$. It is noteworthy that even in this case the differences between the simulation and the analytical model at large scales is of order of $20 - 30\%$ whereas the box-size effect changes the clustering amplitude by more than an order of magnitude at some scales. Thus we may state that the model captures the essence of the box-size effects at large scales.

4.3 Skewness

The lower two rows in Figure 4 show the corresponding plots for $S_3$, shown here as a function of scale. Apart from the lines that show $S_3$ from simulations (thick lines) and our analytical estimate for the weakly non-linear regime (thin lines), we also show the value of $S_3$ expected in the weakly non-linear regime in absence of any finite box size effects for the three series of simulations. The analytical estimate of $S_3$, computed using Eqn.(3) matches well with the values in N-Body simulation at large scales. It is noteworthy that the match between the two is better for a larger cutoff in wave numbers. We believe that this is due to sparse sampling of the initial power spectrum at scales comparable to the box size and due to this our approximation of the sum over wave modes by an integral is not very good.

4.4 Mass Function

Figure 5 shows the number density of haloes for the three series of simulations as a function of mass of haloes. The haloes have been identified using the Friends of Friends (FOF) method with a linking length of 0.1 in units of the grid length. Plotted in the same panels are the expected values computed using the Press-Schechter mass function with a correction for the finite box size.

For each series of simulations, and at each epoch, we fitted the
Figure 6. The first two rows show the pair velocity as a function of distance, and the lowest two rows show the pair velocity as a function of average two point correlation function. The first and third row represent the early epoch and second and fourth row represent the later epoch. In all panels models with $k_c = k_f$ (A1, B1 and C1), $k_c = 2k_f$ (A2, B2 and C2) and $k_c = 4k_f$ (A3, B3 and C3) are represented by the solid, dashed and dot-dashed lines respectively.
Figure 7. The first two rows show the pair velocity dispersion as a function of distance, and the lowest two rows show the pair velocity dispersion as a function of average two point correlation function. The first and third row represent the early epoch and second and fourth row represent the later epoch. In all panels models with $k_c = k_f$ (A1, B1 and C1), $k_c = 2k_f$ (A2, B2 and C2) and $k_c = 4k_f$ (A3, B3 and C3) are represented by the solid, dashed and dot-dashed lines respectively.
Figure 8. The left panel shows the variation in the fractional correction in \( S_3 \), i.e., \( S_{31}/S_{30} \) (see Eqn. (4)), with the index of power spectrum at the scales \( L_{\text{box}}/5 \) (top curve), \( L_{\text{box}}/10 \) (middle curve) and \( L_{\text{box}}/20 \) (lowest line). For a given tolerance of the error in \( S_3 \) due to finite box effects, this gives us the largest scale at which the simulation may be expected to give reliable results. For the middle panel we consider contours of \( C_1 \) at the scale of non-linearity (\( \sigma_8 = 1 \)) for values \( C_1 = 0.01 \) (top curve), 0.03 (middle curve) and 0.1 (lower curve). The contours are plotted on the \( L_{\text{box}}/r_{\text{ad}} - (n + 3) \) plane and indicates the box size required for reliable simulations of a given model. The right panel shows contours of \( S_{31}/S_{30} \) for the \( \Lambda \)CDM model that best fits the WMAP-5 data. Contours shown are for \( S_{31}/S_{30} = 0.01, 0.03 \) and 0.1.

5 SUMMARY

The conclusions of this paper may be summarised as follows:

- We have extended our formalism for estimating the effects of a finite box size beyond the second moment of the density field.
- We have given explicit expressions for estimating the skewness and kurtosis in the weakly non-linear regime when a model is simulated in a finite box size.
• We have tested the predictions of our formalism by comparing these with the values of physical quantities in N-Body simulations where the large scale modes are set to zero without changing the small scale modes.
• We find that the formalism makes accurate predictions for the finite box size effects on the averaged two point correlation function $\xi$ and skewness.
• We find that the formalism correctly predicts all the features of the mass function of a model simulated in a finite box size.
• We studied the effects of a finite box size on relative velocities. We find that the effects on relative velocities mirror the effects on $\xi$.

It is desirable that in N-Body simulations the intended model is reproduced at all scales between the resolution of the simulation and a fairly large fraction of the simulation box. The outer scale up to which the model can be reproduced fixes the effective dynamical range of scales. One would like $S_3$ to be within a stated tolerance of the expected value at this scale. We plot $S_{3\alpha}/S_3$ for power law models at the scale $L_{\text{box}}/20$, $L_{\text{box}}/10$ and $L_{\text{box}}/5$ in the left panel of Figure 8. These are plotted as a function of $n + 3$. It can be shown that this ratio, as also $\sigma_1/\sigma_0$ are functions of scale only through the ratio $r/L_{\text{box}}$. We find that $S_{3\alpha}/S_3$ is some for large negative $n$ and decreases monotonically as $n$ increases. This ratio is smaller than 10% only for $n \geq 0.8$ at $r = L_{\text{box}}/5$. The corresponding number for $r = L_{\text{box}}/10$ is $n \geq -1.6$, and for $L_{\text{box}}/20$ is $n \geq -2.8$. Clearly, the effective dynamic range decreases rapidly as $n + 3 \to 0$. This highlights the difficulties associated with simulating such models.

Similarly, one would like $\sigma^2$ and $\sigma^2_2$ to be comparable at the scale of non-linearity. From requirements of self similar evolution of power law models in simulations, we find that at the scale of non-linearity $C_1 \leq 0.03$ is required for the effects of a finite box size to be ignorable. This gives us a lower bound on $L_{\text{box}}/r_{nl}$ for any given model. The middle panel shows the required $L_{\text{box}}/r_{nl}$ as a function of $n + 3$ for $C_1 = 0.01$, 0.03 and 0.1. Here $C_1$ is the asymptotic value of $\sigma^2_{nl}$ at $r \ll L_{\text{box}}$ and is a fairly good approximation at small scales. We find that the required $L_{\text{box}}/r_{nl}$ for $n = -2$ is more than 100 for $C_2 \geq 0.03$ at the scale of non-linearity. Thus we need a simulation with $L_{\text{box}} \geq 10^3$ if we are to probe the strongly non-linear regime ($\xi \gg 100$) with a degree of confidence. Requirements for models with $n < -2$ are much more stringent, and for models like $n = -2.5$ even the largest simulations cannot be used to study the asymptotic regime.

To put things in context for the favoured cosmological model, the right panel in Figure 8 shows contours of $S_{3\alpha}/S_3$ in the $r = L_{\text{box}}$ plane for the $\Lambda$CDM model that best fits the WMAP-5 data (Dunkley et al. 2008). We find that in order to ensure that the error in skewness is less than 10% at a scale of 10 h$^{-1}$Mpc, we need a simulation box of more than 200 h$^{-1}$Mpc. The required box size is much bigger if the tolerance on error in skewness is smaller. This is a very stringent requirement for simulations of the epoch of reionization where one would like to get the clustering right at the scales of a few Mpc.

Given that the formalism we have proposed works well when compared with simulations, and the fact that calculations in this formalism are fairly straightforward, we would like to urge the cosmological N-Body simulations community to make use of this formalism. We would like to request simulators to report the fractional corrections to the linearly extrapolated amplitude of clustering and the fractional correction to skewness across the range of scales of interest. This will enable users of simulations to assess potential errors arising due to a finite simulation volume.

ACKNOWLEDGEMENTS

Numerical experiments for this study were carried out at a cluster computing facility in the Harish-Chandra Research Institute (http://cluster.mri.ernet.in). This research has made use of NASA’s Astrophysics Data System. We would like to thank T. Padmanabhan for useful discussions. We thank the anonymous referee for useful comments and suggestions.
