**ABSTRACT**

The crystal structure of the Tl⁺ form of the G-quadruplex formed from the *Oxytricha nova* telomere sequence, d(G₄T₄G₄), has been solved to 1.55 Å. This G-quadruplex contains five Tl⁺ ions, three of which are interspersed between adjacent G-quartet planes and one in each of the two thymine loops. The structure displays a high degree of similarity to the K⁺ crystal structure [Haider et al. (2002), *J. Mol. Biol.*, 320, 189–200], including the number and location of the monovalent cation binding sites. The highly isomorphic nature of the two structures, which contain such a large number of monovalent binding sites (relative to nucleic acid content), verifies the ability of Tl⁺ to mimic K⁺ in nucleic acids. Information from this report confirms and extends the assignment of ²⁰⁵Tl resonances from a previous report [Gill et al. (2005), *J. Am. Chem. Soc.*, 127, 16 723–16 732] where ²⁰⁵Tl NMR was used to study monovalent cation binding to this G-quadruplex. The assignment of these resonances provides evidence for the occurrence of conformational dynamics in the thymine loop region that is in slow exchange on the ²⁰⁵Tl timescale.

**INTRODUCTION**

G-quadruplexes are four-stranded structures formed from DNA or RNA sequences containing tandem G-rich repeats. Sequences capable of forming G-quadruplexes *in vitro* have been identified in the telomeres of various organisms (1–9) where they are typically separated by short stretches of pyrimidines. Their location within telomeric DNA sequences has lead to the proposal that G-quadruplexes may be responsible for maintaining chromosomal integrity and chromatid pairing during mitosis (10). G-quadruplexes have also been the target of cancer research (11–14) because telomerase, the ribonucleoprotein responsible for telomere maintenance, is often found at elevated levels in cancerous cells (15,16). Other sequences shown to form G-quadruplexes *in vitro* have been identified in immunoglobulin switch regions (17) and in several gene promoters (18,19); however the biological relevance of these sequences has yet to be demonstrated conclusively.

G-quadruplexes are characterized by consecutive stacks of four planar, hydrogen-bonded guanine nucleotides, called G-quartets (Figure 1). The number of G-quartets contained within a single quadruplex varies, as does the number of distinct oligonucleotide strands that comprise the quadruplex. If less than four separate strands are involved, they fold back upon themselves leaving pyrimidine-rich unpaired loops. There is a considerable amount of heterogeneity in the location and conformation of these loops structures.

G-quadruplexes are stabilized by the binding of monovalent cations, such as Na⁺, K⁺, NH₄⁺, Rb⁺ and Tl⁺ (2,5,20–32). However, the number and location of these binding sites appears to be cation specific. K⁺, NH₄⁺, Rb⁺ and Tl⁺ ions bind between adjacent G-quartet planes (23,24,27,28,30–32). Na⁺, presumably because of its smaller ionic radius, has been reported to bind both between consecutive G-quartet planes and within a single plane, although single plane binding may be preferred (2,26,28,30,33). K⁺ has also been observed bound to G-quadruplex loops (23), while NH₄⁺ reportedly does not bind to the loops of the same G-quadruplex (31).

We recently reported the use of ²⁰⁵Tl NMR to directly study the binding of ²⁰⁵Tl⁺ to the G-quadruplex formed from the *Oxytricha nova* telomere sequence, d(G₄T₄G₄)₂ (34), whose solution structure in the presence of Na⁺ was first reported by Smith and Feigon (5). Tl⁺ is a K⁺ surrogate with the advantage of being a spin-1/2 nucleus with a high gyromagnetic ratio. Thus, its binding to biomacromolecules can be directly observed by solution NMR. The ²⁰⁵Tl directly detected NMR spectrum of d(G₄T₄G₄)₂ contained a cluster of four downfield resonances (described as peaks 1–4, Figure 2A) that correspond to ²⁰⁵Tl⁺ ions bound specifically by the G-quadruplex, and an intense upfield peak resulting from ²⁰⁵Tl⁺ free in solution (data not shown) (34). Peaks
2 and 3 were assigned to the outer and inner binding sites, respectively, (Figure 2B) within the G-quadruplex channel based on the identities of observed $^1$H–$^{205}$Tl scalar couplings. Only one peak was observed for the outer binding site because a rotational symmetry operator bisects the region between the centermost two G-quartet planes of d(G4T4G4)$_2$. $^1$H–$^{205}$Tl scalar (J) couplings were not observed for two of the $^{205}$Tl resonances, therefore their assignment in the G-quadruplex structure could not be definitively ascertained.

Based on crystallographic studies of monovalent binding to G-quadruplexes, the most likely assignment for the remaining $^{205}$Tl peaks is in the thymine loops and/or along the G-quadruplex grooves. The presence of K$^+$ ions in the thymine loops was predicted based on NMR studies of a related G-quadruplex, d(G5CT5G5C)$_2$ (35), and is consistent with a crystal structure of the K$^+$-form of d(G4T4G4)$_2$ (23). However, solution studies of $^{15}$NH$_4$+-form indicated that only three ammonium ions, all inside the G-quadruplex channel, are coordinated by d(G4T4G4)$_2$ (31). There are also examples of monovalent cation binding, including Tl$^+$, in both the major (36,37) and minor (25,36,38–40) grooves of B-form DNA duplexes. Thus, despite their importance for G-quadruplex formation, the interaction of monovalent cations with these structures remains somewhat ambiguous.

To gain a greater understanding of monovalent cation binding to nucleic acids, to further demonstrate the ability of Tl$^+$ to specifically mimic K$^+$, and to complete the assignment of unknown $^{205}$Tl resonances, we have crystallized the Tl$^+$-form of d(G4T4G4)$_2$ and determined the location of all Tl$^+$ binding sites. When considered in light of this crystallographic data, we propose that the unassigned peaks in the $^{205}$Tl NMR spectrum of d(G4T4G4)$_2$ provide spectroscopic evidence for the occurrence of conformational dynamics within the loop region.

**MATERIALS AND METHODS**

**Crystallization conditions**

DNA oligonucleotides d(GGGGTTTTGGGG) were purchased (W. M. Keck Facility, Yale University) and desalted using Sep-Pak C$_{18}$ cartridges (Waters, USA) and eluted with 40% (v/v) acetonitrile/water. After lyophilization, the DNA was dissolved to a final concentration of 10 mM in H$_2$O.

The crystallization conditions are listed in Table 1. The crystallization buffer, 50 mM potassium cacodylate, was made by adjusting the pH of cacodylic acid to 6.5 using potassium hydroxide and then diluting the solution to the appropriate concentration (50 mM). The final concentration of K$^+$ in the buffer was ~85 mM.

G-quadruplex formation was facilitated by heating d(GGGGTTTTGGGG), potassium acetate, potassium cacodylate and H$_2$O to 358 K for 15 min followed by slow cooling to 277 K. The DNA concentration during annealing was ~2.14 mM. After annealing, appropriate amounts of magnesium acetate, spermine and 2-methyl-2,4-pentanediol (MPD) were added to the crystallization solution, making the final DNA concentration 1.5 mM. The solution was then centrifuged at 14 000 g for 30 min to remove any precipitate. Crystals were grown...
Thallium binding sites were determined after molecular replacement based on the presence of large, unoccupied peaks present in both the 2Fo − Fc and anomalous maps. The thallium ions were assigned to regions containing strong density in the anomalous map. Coot was used for water assignment and viewing of all density maps (47). The PDB accession code for the structure is 2HBN.

**NMR CPMG-relaxation dispersion experiments**

NMR experiments were performed on a 14.1 T Varian Inova instrument equipped with a triple-resonance room temperature probe and xyz gradients at an experimental temperature of 10°C. The temperature was calibrated with 100% methanol. Relaxation dispersion experiments (48) were performed on the methyl groups of thymine using a 2.5 mM sample of the G-quadruplex d(GGGTTTTGGGG) containing 50 mM thallium acetate. The NMR experiment was of the constant relaxation time version (49) with the 1H and 13C carrier frequencies placed at 1.5 and 14 p.p.m., respectively during the relaxation period. CPMG delays were 0.625, 0.714, 1.0, 1.25 (× 2), 1.67 (× 2), 3.33, 2.5 (× 2), 5.0 and 10.0 ms. Peak intensities were determined in NMRRdraw (50) using the script autoFit.tcl provided with the program. Dynamics parameters were obtained by fitting dispersion equations to the experimentally determined relaxation rates as described previously (51). Methyl assignments at this lower temperature were determined by monitoring the NMR chemical shifts in a two-dimensional 13C HSQC in a temperature series from 25 to 10°C.

**RESULTS**

**Structure determination and features**

The crystal structure of the Tl+–form of d(G4T4G4)2 was solved to 1.55 Å from a single crystal. We were able to obtain crystals of the K+–form using conditions (Table 1) similar to those reported by Neidle and coworkers (23) except that acetate versions were substituted for all chloride-containing crystallization components to avoid the formation of insoluble thallium chloride in later steps. The concentrations of spermine (3.5 mM) and DNA oligonucleotide (1.5 mM) were slightly different from those used for crystallization of the K+–form (4.10 and 1.0 mM, respectively). The K+–form was then converted to the Tl+–form by soaking the crystals in 50 mM thallium acetate. Attempts were also made at crystallizing the Tl+–form of d(G4T4G4)2 directly by substituting various concentrations of thallium acetate for potassium acetate in the crystallization solution. However, no crystals were produced from these efforts.

Experimental phases were determined by molecular replacement using the crystal structure of the K+–form (PDB 1JRN) (23). Like the orthorhombic K+–form, the Tl+–form was solved in the space group P212121 with unit cell dimensions that differ from the K+–form by only 0.3–3.2% in all dimensions (Table 2). Each asymmetric unit contains two G-quadruplexes that have an RMSD of 0.24 Å. The thymine loops facilitate intermolecular packing within both the asymmetric unit and crystal lattice by forming a pair of pseudo 2-fold related hydrogen bonds between the T6 O4

### Table 1. Crystallization conditions for the Tl+–form of d(G4T4G4)2

| Crystallization components | Potassium cacodylate pH 6.5 (mM) | 50.0 |
|---------------------------|---------------------------------|------|
| Magnesium acetate (mM)    | 10.0                            |      |
| Potassium acetate (mM)    | 40.0                            |      |
| Spermine (mM)             | 3.5                             |      |
| DNA (mM)                  | 1.5                             |      |
| MPD (% v/v)               | 5.0                             |      |
| MPD (% v/v) in well        | 35.0                            |      |
| Soaking and cryoprotection |                                 |      |
| Thallium acetate (mM)     | 50.0                            |      |
| MPD (% v/v)               | 60.0                            |      |

**Table 2. Crystallographic data for the Tl+–form of d(G4T4G4)2**

| Crystallographic data                  |  |
|---------------------------------------|---|
| Space group                           | P212121 |

...using the hanging drop method (2 µl drops) at 291 K and appeared after 6–8 weeks as clear, rod-like crystals. The crystals were soaked in solutions containing 60% MPD and 50 mM thallium acetate for 2 h at 291 K prior to freezing in liquid nitrogen.

**Structure determination**

Data were collected on beamline X25 at the National Synchrotron Light Source at 0.9780 Å wavelength and diffraction was observed to 1.55 Å. The data were integrated and scaled using the HKL 2000 package (41). Experimental phases were determined using molecular replacement with the orthorhombic crystal structure determined by Neidle and coworkers (23) (PDB 1JRN). The space group (P212121) and unit cell dimensions were similar to the published structure (Table 2). Refinement was performed using Refmac5 (42–45) in the CCP4 program suite (46). Several cycles of rigid body refinement were followed by restrained refinement using TLS parameters, resulting in an R-factor of 24.9%. One final round of restrained refinement was performed using anisotropic B-factors, further reducing the R-factor to 22.7%.

...structure is 2HBN.
from one G-quadruplex and the T8 N3 from the neighboring G-quadruplex (Figure 3).

The thallium ions

The assignment of metal binding sites was facilitated by the presence of strong anomalous peaks (>5.7σ) (Figure 4). Each G-quadruplex contains five bound Tl⁺ ions, three interdigitated between G-quartet planes and one in each of the two loops. The average spacing between each Tl⁺ ion is 3.6 Å. The relative positions of these five metals are very similar to those found in the K⁺ crystal structure, where the average metal–metal spacing is reported to be 3.4 Å (23). The Tl⁺ ions located between two successive G-quartet planes are coordinated by eight oxygens (one O6 from each of the surrounding guanines). These coordination distances range from 2.5–3.3 Å, which are similar to those observed in the K⁺ structure (2.6–3.1 Å) (23). The Tl⁺ ions bound to the loops are coordinated by four guanine O6 carbonyls from the outer G-quartet plane and two thymine carbonyls (T5 and T7 O2). The absence of any other regions of anomalous density in the vicinity of these coordination oxygens indicates that there are only five ordered Tl⁺ binding sites (Figure 4).

The average B-factors for the loop-associated metals (39 Å²) are higher than the other thallium binding sites (28 Å²). Smaller differences in B-factors are observed in the K⁺-form of d(G₄T₄G₄)₂ (23) and very similar to the K⁺ X-ray structure (23) and very similar to the K⁺ X-ray structure (23). This is likely related to the use of different criteria for the assignment of water peaks.

The G-quartets and grooves

Each G-quartet is formed by hydrogen bonding along the Hoogsteen and Watson–Crick faces of the guanine (N2–N7 and N1–O6) with average bond lengths of 2.9 and 2.8 Å, respectively. The guanine bases have alternating syn–anti glycosidic bond angles and all thymines are in the anti conformation. The position of G4 deviates slightly from the outer G-quartet plane in each of the outer G-quartets. This displacement allows G4 to stack with the subsequent thymine (T5). Each G-quartet is formed by hydrogen bonding along the phosphate backbone, indicating that there are only five ordered Tl⁺ binding sites (Figure 4).

The waters

A total of 44 waters were assigned to each asymmetric unit. The assignments were made in regions of unassigned density (>1.0σ) in the 2Fₒ – Fc maps that did not have any anomalous density. The number of assigned waters is considerably less than the number reported (230) for the crystal structure of the K⁺-form (23). This is likely related to the use of different criteria for the assignment of water peaks.

With respect to cation coordination, previous studies have identified that two waters participating in the coordination of the K⁺ ions bound within the thymine loops in the crystal structure of d(G₄T₄G₄)₂ (23). Consistent with those studies, in the structure reported here one of the assigned waters in the Tl⁺-form of d(G₄T₄G₄)₂ is located within the thymine loops and in close proximity to the loop-associated Tl⁺ ion. The water–metal distance is 3.1 and 4.2 Å for the two respective G-quadruplexes located in the asymmetric unit. A second region of density within the thymine loop region was also initially assigned as water; however, this assignment could not be confirmed in our structure because the density is not resolved from the nearby Tl⁺ density. Accordingly, this water assignment was deleted.
Comparison to other structures

The G-quadruplex is a homodimer containing diagonal thymine loops at both ends (Figure 5A and B). This architecture is identical to that observed in the solution structures (Na⁺, K⁺, Tl⁺ and NH₄⁺) of d(G₄T₄G₄)₂ (5,20–22,34), in the crystal structure of the Na⁺-form in the O.nova protein complex (2), and in the orthorhombic and trigonal crystal structures of the K⁺-form reported by Neidle and coworkers (23). The average RMSD of the Tl⁺ crystal and K⁺ crystal forms is 0.26 Å. The high degree of similarity between these two crystal structures is a likely explanation for the limited effect that soaks in high concentrations of thallium (<50 mM) have on the structural resolution.

The RMSD of the Tl crystal structure to the solution structure of the Tl⁺-form of d(G₄T₄G₄)₂ (PDB 2AKG) is 2.16 Å (34); however, the G-quartets have an RMSD of only 1.25 Å. This suggests that the loop region is the source of the greatest amount of variability between the X-ray and solution structures (Figure 6A). In the crystal structure of the Tl⁺-form, T8 is extended into solution, similar to the crystal structures of the K⁺- (Figure 6B) and Na⁺-forms (2,23). This is in contrast to the Tl⁺ (and K⁺) solution structures where T8 stacks above the neighboring G-quartet plane. This conformation in solution is supported by unambiguous NOEs between T8 and the G-quartet plane (G1, G4 and G12) (34). However, the presence of telomere binding protein precludes packing between G-quadruplexes in the crystal structure of the Na⁺-form (2), indicating that monovalent metal identity may also play a role in defining the loop conformation.

NMR dynamics

The relative ¹H and ¹³C peak positions of the thymine methyl do not change between 25 and 10°C and therefore their assignment is straightforward at 10°C (Figure 7A).
NMR relaxation dispersion experiments show evidence of conformational exchange at the methyl position of T5 in the d(G4T4G4)2 structure (Figure 7B). At 10°C, the conformational exchange rate, $k_{ex} = 2900 \pm 410 \text{ s}^{-1}$ and $R_{ex} = p_{Dw} A\mu^2 = 2.0 \pm 0.4 \text{ s}^{-1}$. At this static magnetic field strength, there is no evidence of dynamics at the other methyl positions in the thymine loops (Figure 7B).

**DISCUSSION**

**Tl⁺ binding sites in d(G₄T₄G₄)₂**

The crystal structure of the Tl⁺-form of d(G₄T₄G₄)₂ is very similar to the K⁺ crystal structure (23), even in variable regions, such as the thymine loops, and the monovalent cation binding sites. These structural similarities and the ability of such a large number of thallium ions to replace potassium ions without disrupting the crystal lattice further verifies the isomorphous nature of Tl⁺ and K⁺ in nucleic acids (34,57–60) and suggests its usage as a heavy metal derivative in crystallographic studies and as a monovalent ion probe (24,25,34) is valid and non-perturbing.

The Tl⁺-form of d(G₄T₄G₄)₂ is capable of binding three Tl⁺ ions within the G-quadruplex channel and two in the thymine loops. The observation of Tl⁺ ions associated in the thymine loops is in agreement with the K⁺ crystal structure (23) but not with solution studies of ¹⁵N₄H₄⁺ binding to d(G₄T₄G₄)₂ (20,31). Possible explanations that reconcile these data are that the thymine loops of d(G₄T₄G₄)₂ do not adopt a conformation in solution that can accommodate the binding...
of any monovalent cations or that ammonium binds to d(G₄T₄G₄)₂ in a manner that is somewhat different from K⁺ and Tl⁺.

**Thymine loop conformation**

Because the loops mediate crystal packing and are the only region that differs (albeit only slightly) from the solution and crystal structures of both K⁺- and Tl⁺-forms, it is possible that the crystal conformation does not exist in solution and that the metal bound by the thymine loops is a crystallographic artifact. However, the involvement of this conformation in crystal packing does not rule out its existence in solution. The thymine loops have increased transverse relaxation rates (34), indicating the presence of conformational exchange in this region. Further evidence of their dynamic nature is provided by the slightly elevated B-factors observed in the loops relative to the G-quartets (Table 2). Accordingly, it is reasonable to conclude that the loop conformation observed in the crystal structure is one of several that exist in solution.

**Assignment of ²⁰⁵Tl NMR resonances**

These combined crystallographic and NMR dynamics experiments can be used to gain insight into the G-quadruplex structure and to refine the assignment of ²⁰⁵Tl resonances from the recent NMR solution study of ²⁰⁵Tl⁺ binding to d(G₄T₄G₄)₂ (34). Based on these experiments, ²⁰⁵Tl peak 1 (Figure 2) is likely binding in the thymine loops, given that ordered Tl⁺ binding sites exist in the loop regions of the crystal structure. The high degree of occupancy in these binding sites is consistent with the approximate area of peak 1 relative to peaks 2 and 3.

The assignment of ²⁰⁵Tl peak 4, which is of lower intensity, is less straightforward. No anomalous density was observed along the G-quadruplex grooves, making it unlikely that this is the explanation for the resonance corresponding to peak 4. The monovalent binding sites located within the G-quadruplex channel correspond to peaks 2 and 3 (34). Further, each of these sites displays ¹H–²⁰⁵Tl scalar couplings, which were not observed for peak 4. Thus, it is not likely that peak 4 results from ²⁰⁵Tl⁺ binding to the G-quadruplex channel. One remaining possibility is that peaks 1 and 4 correspond to a single Tl⁺ ion bound to a conformationally mobile thymine loop resulting in two, distinct ²⁰⁵Tl resonances separated by 40 p.p.m., which is reasonable considering the extremely large ²⁰⁵Tl chemical shift range (~7000 p.p.m.) (61). This assignment to the thymine loop is in agreement with the aforementioned data indicating that these loops are in conformational exchange and could also be the reason that ¹H–²⁰⁵Tl scalar couplings were not observed for peaks 1 and 4.

However, the assignment of two ²⁰⁵Tl peaks to the loop binding sites initially seems inconsistent with the symmetry of this G-quadruplex (25,31,34). Because of this 2-fold symmetry, only one ¹H resonance is observed for each proton in the G-quartet and in the loop (5,20–22,34). In addition, only a single ²⁰⁵Tl resonance is observed for the ²⁰⁵Tl⁺ ions bound to the two outer G-quadruplex binding sites (34). Thus, the Tl⁺ binding sites located in the thymine loops would be expected to be magnetically equivalent as well, resulting in only one ²⁰⁵Tl peak for the loop-associated binding sites.

This apparent discrepancy can be explained by taking note of the more generous limit on slow conformational exchange imposed by the large ²⁰⁵Tl chemical shift range. The appearance of a resonance in an NMR spectrum for a nucleus in a conformational exchange process depends on the relation between the rate of exchange (kex) and the chemical shift difference (Δω) for the assumed, two exchanging conformations (62). If the exchange rate is less than Δω (slow exchange) two resonances are observed at the chemical shift values of the individual conformations. If, on the other hand, kex > Δω (fast exchange) a single resonance is observed at a population weighted chemical shift. We propose that peaks 1 and 4 (Figure 2A) are in the slow exchange regime (two peaks) on the thallium chemical shift timescale whereas the ¹H resonances in these conformational mobile loops are in the fast exchange regime (one peak), thereby resolving the noted discrepancy. This allows estimation of the time scale for conformational motion of these loops. At 25°C, the separation between the two downfield ²⁰⁵Tl resonances (peaks 1 and 4) is ~40 p.p.m., Δω ≈ 72 000 s⁻¹ at 11.7 T, thereby placing an upper limit on the exchange rate for a slowly exchanging thallium ion. Even if a generous chemical shift difference of 2 p.p.m. is considered for an exchanging proton, Δω ≈ 6000 s⁻¹ at 11.7 T, which is 1/12 of the limit on the ²⁰⁵Tl timescale. This places a lower limit on the exchange rate on the ¹H time scale. Thus, it is possible that a conformationally exchanging thymine loop could be moving on a timescale that would give rise to slow exchange on the ²⁰⁵Tl timescale and fast exchange on the ¹H timescale if the exchange rate was between 10⁻³–10⁴ s⁻¹. In order to observe two separate ¹H resonances in an exchange process on this time scale they would have to be separated by over 22 p.p.m., which is larger than the diamagnetic ¹H chemical shift range.

To obtain experimental evidence concerning the thymine loop dynamics, NMR relaxation dispersion experiments were performed (63). Because the thallium signal-to-noise is insufficient to accurately measure conformational exchange on this timescale, we attempted to characterize the loop dynamics by using CPMG-dispersion experiments at the methyl positions in the thymine loop residues. If these loops are dynamic the methyl position should be sensitive to its motion. The data in Figure 7B clearly show increasing (dispersion) R₂(1/τ₂p) values for T5 as the spin-echo delay increases. The resulting dynamics parameters indicate an exchange rate for T5 of 2900 s⁻¹ at 10°C. If the exchange rate at 25°C is estimated by the so-called ‘Q₁₀ = 2’ rule (64) kex would be ~10 000 s⁻¹, a rate in line with the argument of a motional process in slow exchange with respect to thallium but fast on the proton chemical shift time scale. It should be noted that the exact exchange rate at 25°C (the temperature at which ²⁰⁵Tl NMR experiments were performed) is not known. For technical reasons the CPMG-dispersion experiment cannot determine exchange rates >10⁷ therefore they were performed at a lower temperature where the exchange rate was estimated to be in the measurable range based on our calculations and observations at 25°C. This conclusion suggests that the areas of peaks 1+4 should equal peak 2 (and 2 × peak 3). Quantitation of peak areas is difficult
due to the large linewidths, baseline distortions from the large free TI resonance, disordered TI binding along the quadruplex grooves, and the non-Lorentzian shape of peak 4. Nevertheless considering all these factors, qualitative estimates provide peak areas consistent with the exchange scenario described above. In summary the dispersion experiments are completely consistent with a flexible thymine loop resulting in a thallium nucleus experiencing two distinct magnetic environments on a time scale that allows observation of separate $^{205}$TI resonances.

We have crystallized the TI$^+$-form of d(G$_3$T$_3$G$_3$)$_2$ and demonstrated that it binds five TI$^+$ ions in a manner that is nearly identical to the previously reported K$^+$ crystal structure (23). These results demonstrate that $^{205}$TI$^+$ ions bind within the G-quadruplex thymine loops in a manner similar to K$^+$ and are observable by direct detection $^{205}$TI NMR (34). The combination of knowledge from X-ray crystallography and solution NMR of all existing TI$^+$ binding sites has led to the proposal that multiple loop conformations exist, at least two of which bind TI$^+$. The complementary nature of these two spectroscopic techniques provides additional insight on monovalent cation binding to the conformationally flexible G-quadruplex.

ACKNOWLEDGEMENTS

The authors thank M. Becker and the staff at Brookhaven National Laboratory Beamline X25 for help with data collection and the staff at the Yale University Center for Structural Biology, especially Dr Michael Strickler, for help with refinement. Jesse Cochrane, Mary Stahley and Sarah Lipchock provided helpful scientific discussion. This research was supported by NIH R01 GM61239 to S.A.S. and J.P.L. M.L.G. acknowledges support from an NSF graduate fellowship. Funding to pay the Open Access publication charges for this article was provided by NIH R01 GM61239.

Conflict of interest statement. None declared.
