ABSTRACT

We report on the serendipitous discovery of a new transient in NGC 5907, at a peak luminosity of $6.4 \times 10^{39}$ erg s$^{-1}$. The source was undetected in previous 2012 Chandra observations with a $3\sigma$ upper limit on the luminosity of $1.5 \times 10^{38}$ erg s$^{-1}$, implying a flux increase of a factor of > 35. We analyzed three recent 60ks/50ks Chandra and 50ks XMM-Newton observations, as well as all the available Swift/XRT observations performed between August 2017/March 2018. Until the first half of October 2017, Swift/XRT observations do not show any emission from the source. The transient entered the ULX regime in less than two weeks and its outburst was still on-going at the end of February 2018. The 0.3–10 keV spectrum is consistent with a single multicolour blackbody disc ($kT > 1.5$ keV). The source might be a black hole accreting at the Eddington limit. However, although we did not find evidence of pulsations, we cannot rule-out the possibility that this ULX hosts an accreting neutron star.

Key words: accretion, accretion discs - X-rays: binaries - X-Rays: galaxies - X-rays: individual: NGC 5907 ULX-2.

1 INTRODUCTION

Ultraluminous X-ray sources (ULXs, e.g. Kaaret et al. 2017) are a class of extragalactic point like sources, with X-ray luminosities higher than $10^{39}$ erg s$^{-1}$ up to, in the most extreme cases, $10^{42}$ erg s$^{-1}$ (e.g. HLX-1; Farrell et al. 2009). Such luminosities are hence well above the Eddington limit for accretion of pure hydrogen onto a 10 M$\odot$ black hole (BH). The number of known ULXs is still increasing and nowadays more than 300 sources are confirmed ULXs, as catalogued e.g. by ROSAT (Liu & Bregman 2005), Chandra (Swartz et al. 2011) and XMM-Newton (Walton et al. 2011).

ULXs represent a current hot topic of X-ray astronomy because of their peculiar accretion properties. It is believed that ULXs are accreting compact objects in binary systems (e.g. Motch et al. 2014; Urrutah et al. 2018), but the nature of the compact object is still under debate: indeed ULXs may host either i) intermediate mass BH (IMBHs, 100 – 10$^5$ M$\odot$; Colbert & Mushotzky 1999) accreting well below the Eddington limit, or ii) stellar BHs (5 M$\odot$ $< M_{BH} < 80$ M$\odot$; e.g. Zampieri & Roberts 2009; Gladstone et al. 2009; Walton et al. 2013; Middleton et al. 2015) or iii) even neutron stars (NSs), accreting at extremely super Eddington rates (e.g. Israel et al. 2017).

However, it is now thought that the vast majority of the ULX population is composed of super-Eddington accreting compact objects. In particular, the presence of NSs in at least 4 ULXs is confirmed by the detection of pulsation (Bachetti et al. 2014; Israel et al. 2017a; Fürst et al. 2016; Israel et al. 2017b, Carpano et al. 2018). In addition, these pulsating ULXs (PULXs) show significant flux variability of several orders of magnitude. The variety of possible compact objects in ULXs suggests they are a manifold population hosting both BHs and NSs (e.g. Middleton & King 2017), although their relative number is still highly uncertain.

Here we report the discovery of a new X-ray transient in the direction of the galaxy NGC 5907 (Figure 1), located at a distance of 17.1 Mpc (Tully et al. 2013). NGC 5907 hosts a large population of X-ray sources, with the brightest being the PULX NGC 5907 X-1 (e.g. Sutton et al. 2013; Walton et al. 2016; Israel et al. 2017).
The new source reported here could be the second ULX hosted in this galaxy.

2 DATA REDUCTION

Chandra. We analyzed two Chandra ACIS-S archival observations of 11th February 2012 (Obs.ID: 12987, 14391). We also obtained, as Director Discretionary Time (DDT), three ACIS-S observations (Obs.ID: 20830, 20994, 20995) taken on 7th November 2017, 28th February and 1st March 2018. The Chandra observation exposure times are ∼17 ks, ∼14 ks, ∼52 ks and ∼16 ks, respectively. Chandra data were reduced with CIAO v.4.9 and calibration files CALDB v.4.7.6. The source events were chosen from a circular region of radius 3″, while the background was selected in a circular region of radius 15″ and free of sources. We obtained source spectra with the CIAO task SPECEXTRACT, which creates the appropriate response/auxiliary files for the spectral analysis. With the PILEUP_MAP tool, we estimated that pile-up effects contribute to ∼1%, and we can neglect it. Because of their close temporal proximity, the 2018 observations were analyzed as a single dataset.

Swift. We analyzed all the available (24) XRT observations of the Neil Gehrels Swift Observatory taken between August 2017 and March 2018, with an average exposure time of ∼2 ks. These observations are generally spaced at intervals of about one week. We reduced the data with XRTPipeline and extracted 0.3–10 keV lightcurves selecting circular regions of radii 20′′ and 130′′ for source and background, respectively. We also analyzed UVOT data by reducing them with standard procedures.

XMM-Newton. On 2nd December 2017, we obtained a DDT XMM-Newton observation with a total exposure time of 60 ks. We extracted the data from EPIC-pn and the two EPIC-MOS cameras, and reduced them with SAS v.15.0.0. We selected single- and double-pixel events (PATTERN=4), and single- and multiple-pixel events (PATTERN=12), for pn and the MOS, respectively. We removed high background time intervals and we obtained net exposure times of ∼38 ks in the pn and ∼58 ks in the MOS. For spectral and timing analyses, we extracted the source and background events from circular regions of radii 30′′ and 60′′, respectively.

HST. We analysed optical images of the field collected with the Hubble Space Telescope (HST). The field was observed with the Wide Field and Planetary Camera 2 (WFPC2) instrument on 1996, March 31 in the F450W (λ = 4556Å, ∆λ = 951Å) and F814W (λ = 8012Å, ∆λ = 1539Å) filters, and on 2007, October 1 in the F606W filter (λ = 5997Å, ∆λ = 1502Å), with exposure times of 2340 s, 960 s and 3400 s, respectively. We retrieved calibrated, geometrically-corrected images from the Hubble Legacy Archive (HLA) – such images have an improved astrometry based on cross-correlation with the Sloan Digital Sky Survey catalogue, with r.m.s. accuracy of ∼0.1″ per coordinate. We carried out a source detection using the SExtractor software (Bertin & Arnouts 1996) and we converted count rates to magnitudes in the ST system using the photometric calibration provided by the HLA pipeline.

3 RESULTS

In the 2017 Chandra ACIS-S image, we detected a new bright X-ray source which was not present in the same field in the 2012 Chandra observation (right inset in Figure 1). The most precise
3.1 Temporal analysis

In the 2012 Chandra observations, ULX-2 was not detected, with a 3σ upper limit of $4.4 \times 10^{-15}$ erg cm$^{-2}$ s$^{-1}$ on the 0.3–10 keV flux (assuming a multicolour blackbody disc, see below). The transient was undetected also in all the Swift/XRT observations taken before 15th October 2017. Stacking the August/September observations we obtained a 3σ upper limit of $2.2 \times 10^{-14}$ erg cm$^{-2}$ s$^{-1}$ on the average flux (shown in Figure 2-left). A source consistent with the position of ULX-2 was detected in later Swift/XRT observations taken at the end of October till the half of February 2018. Because of the angular resolution of Swift/XRT ($\sim 18''$ HPD), we cannot exclude that other sources, very close to ULX-2, became active in the same period. However, if we associate the Swift/XRT source with ULX-2, these findings suggest that it entered the ULX regime in the second half of October 2017.

The 0.3–10 keV background-subtracted 2017 Chandra lightcurve of ULX-2, is shown in Figure 2-right (top panel). A fit with a constant flux gives $\chi^2/\text{dof} = 46/10$, indicating the presence of variability (for timescales >5000s). On the other hand, we found that, both during the XMM-Newton and 2018 Chandra observations, the source had a rather constant flux ($\chi^2/\text{dof} = 12.1/11$ and $\chi^2/\text{dof} = 5.3/6$; Fig. 2-center, bottom panel). We also investigated, in both XMM and Chandra data, the hardness ratio between the energy bands 0.5–1.5 keV (soft) and 1.5–10 keV (hard) which indicates no significant spectral variability.

We then created a power spectrum (only for the XMM-Newton and 2017 Chandra observations, because of the too low 2018 Chandra counting statistics) for the whole energy band (0.3–10 keV) but we could not find any coherent signal in both datasets. Assuming sinusoidal modulation, we derived a 3σ upper limit on the pulsed fraction (defined as the semi-amplitude of the sinusoid divided by the source average count rate) of 60% and 35% for Chandra and XMM-Newton, for periods in the range $\sim$6e–5000s and $\sim$0.140s–150s, respectively. An accelerated search for coherent signals using a grid of 6234 P/P values in the range $\pm 10^{-11}$–$10^{-6}$ s$^{-2}$ gave no statistically significant signals.

3.2 Spectral analysis

As the hardness ratio does not indicate significant spectral variability in the single observations, we extracted an averaged spectrum for the XMM-Newton/EPIC (pn + MOS1/2), and the 2017 and 2018 Chandra data; they collect $\sim$3600, and $\sim$550 and $\sim$95 net source counts, respectively. We rebinned the spectra with at least 20 counts per bin and used XSPEC v.12.8.2 to fit them.

We first analyzed the EPIC spectra and adopted simple models as a POWERLAW, or a BLACKBODY or a DISKBB, absorbed with TBABS and using the abundances of Wilms et al. (2000). We found that acceptable spectral fits ($\chi^2_{\text{red}} < 1$) are obtained with the POWERLAW or the DISKBB (Table 1). However, the POWERLAW model left some skewed residuals (in particular above 5 keV, see Figure 2, right-middle panel). Hence, in the following, we focus on the DISKBB fit (see Figure 2, right-bottom panel). With the latter, we estimated a mean disc temperature of $\sim 1.5$ keV, a total column density of $8 \times 10^{20}$ cm$^{-2}$, hence higher than the Galactic $n_H$ along the source direction ($1.38 \times 10^{20}$ cm$^{-2}$; Dickey & Lockman 1990), and an absorbed 0.3–10 keV flux of $(1.7 \pm 0.1) \times 10^{-12}$ erg cm$^{-2}$ s$^{-1}$. If ULX-2 is in NGC 5907, the flux translates to an unabsorbed luminosity of $\sim 6.4 \times 10^{39}$ erg s$^{-1}$ (for a distance of 17.1 Mpc).

The 2017 Chandra spectrum was then fitted with the DISKBB model with $n_H$ fixed to the column density found in the EPIC spectra. The DISKBB provides a very good fit ($\chi^2_{\text{red}} < 1$), with a disc temperature consistent within the uncertainties with the EPIC value (Table 1). We note that the average ULX-2 absorbed flux during this Chandra observation was $\sim 20\%$ lower ($(1.2 \pm 0.1) \times 10^{-13}$ erg cm$^{-2}$ s$^{-1}$) than that found during the XMM-Newton observation. However, we also checked that the source flux in the last 20 ks of this Chandra observation was consistent with the XMM-Newton one. We also note that, inside the XMM-Newton source extraction region, at least three other weaker sources are included (as seen in the Chandra image). We estimated that they may increase the ULX-

a EPIC absorbed flux in the 0.3–10 keV energy band; b As found in EPIC; values in boldface are statistically acceptable.

2 flux of ≤10% and can possibly affect its spectrum but the contaminant effect on the ULX-2 EPIC spectrum appears very marginal because of the strong agreement with the Chandra data.

Finally, the 2018 Chandra spectrum was still compatible with a DISKBB model (χ^2/ndof = 5.33/6, Table 1). Fixing the column density to 8 × 10^20 cm^-2, we found an inner disc temperature of 1.1 ± 0.3 keV and an absorbed 0.3–10 keV flux of (2.1 ± 0.4) × 10^-14 erg cm^-2 s^-1, i.e. a luminosity of ∼4 × 10^38 erg s^-1 and thus well below the ULX threshold luminosity.

3.3 Optical data

We searched for an optical counterpart inside the X-ray Chandra error circle (radius of 1.3’). In the archival HST/WFPC2 data observations, we found a bright object (Figure 1, inset-right) that we consider as the most promising counterpart candidate, with ST magnitudes of 23.7±0.1, 24.65±0.07 and 24.12±0.09 (absolute magnitudes of −7.5±0.1, −6.51±0.07 and −7.04±0.09) in the F450W, F606W and F814W filters, respectively. Luminosity and colours of this source are consistent with an OB-type star in NGC 5907. We compared the simultaneous F450W and F814W measurements with emission models of ULX binaries (Ambrosi & Zampieri, in prep.). The evolutionary tracks of a binary with a ~20 – 30M⊙ BH and an evolved donor with a main sequence mass of ~20M⊙ are in agreement with the Galactic extinction corrected photometry, and the mass transfer rate is above Eddington. A detailed modelling is under way and will be presented elsewhere.

4 DISCUSSION

The long-term variability, the nH higher than the Galactic column density and the quite hard X-ray spectrum of the newly discovered source disfavour the identification with a star in our Galaxy. In particular, a foreground star of any spectral type and with the X-ray flux of ULX-2 should have an optical magnitude M_V < 18 mag (Krautter et al. 1999). To explore the chance coincidence of a background AGN, we considered the X-ray Log N – Log S of extragalactic sources: the number of AGN per square degree with a flux larger than > 10^-13 erg cm^-2 s^-1 is of the order of a few (e.g. Moretti et al. 2003). For an estimated area of 4.7’×0.5’ covered by NGC 5097, this translates on a number of contaminant AGN less than 5 × 10^-3. This finally rule-out the possibility of a supernova event as no significant UV variability has been seen in UVOT data, where, however, the source contribution cannot be distinguished from the rest of the galaxy.

We therefore conclude that the new source is indeed in all respects a ULX transient in NGC 5907, and its peak luminosity is ~ 6.4 × 10^39 erg s^-1, making this source the second brightest ULX in the galaxy. This implies a luminosity increment of at least a factor of ~35 with respect to the 2012 Chandra upper limit. Before October 2017, it was below the nominal ULX threshold luminosity (> 10^39 erg s^-1) where it returned at the end of February 2018 (L_X = 7 × 10^38 erg s^-1), following an exponential decay with folding time of 27 ± 4 days. We remark that we could investigate the new source properties with XMM-Newton because the close (~2”) ULX-1 was in quiescence and hence not contaminating the ULX-2 emission. Although beyond the scope of this paper, we double-checked all the available XMM-Newton observations of ULX-1 and, through a Maximum Likelihood analysis based on the EPIC pn/MOS PSFs (e.g. Rigosi & Mereghetti 2018) we found hints for the presence of ULX-2 only during the observation of 6 November 2013 (at estimated 0.3–10 keV flux of ~8 × 10^-15 erg cm^-2 s^-1), when ULX-1 was very weak. However, our analysis does not fully account for possible contaminants close to the ULX-2 position, that may affect the reported flux.

ULX spectra, in the so-called UltraLuminous state (Roberts 2007), are generally well described by at least two spectral components interpreted as a soft thermal emission (kT ~ 0.1 – 0.5 keV) from cold optically thick outflows and hard thermal emission from a hot modified accretion disc or corona close to the compact object (e.g. Gladstone et al. 2009; Pintore & Zampieri 2012; Sutton et al. 2013; Bachetti et al. 2014; Middleton et al. 2015; Walton et al. 2016). On the other hand, there is a small sample of ULXs with very limited data quality displaying properties consistent with the spectral states of Galactic accreting black holes X-ray binaries (Sutton et al. 2012). However, some of these ULXs showed the features of the UltraLuminous state when data of better quality became available (e.g. Sutton et al. 2013; Pintore et al. 2016). We believe that this is not the case for ULX-2 because the quality of its current spectra is relatively good (~3500 net EPIC counts).

We found that the average ULX-2 spectrum is described by a single multicolour accretion disc with a temperature of ~1.5 keV, indicating that the source may be in a soft state reminiscent of those found in Galactic accreting BH binaries (e.g. McClintock & Remillard 2006). However, although not supported by the data, we cannot exclude that its disk-like shape might suggest that ULX-2 is in the super-Eddington “very thick-state” (i.e. a spectral shape consistent with Comptonization from an optically thick corona with τ > 10 and KT ~1-2 keV; see Pintore & Zampieri 2012). In any case, if the source is radiating close to the Eddington limit (and we consider the soft state as reliable), the implied mass would be M_BH ~ L_X/(1.38 × 10^38)M_⊙ ~ 30 M_⊙ (assuming isotropic emission). Although the mass of such an object would be larger than any accreting BH found in our Galaxy, the LIGO and VIRGO detectors showed the existence of BHs of similar sizes (Abbott et al. 2016, 2017). Assuming an inclination angle <70° (because of the absence of dips or eclipses), the best-fit DISKBB normalization corresponds to an estimated inner accretion disc radius of <140 km, or to an upper limit of ~15 M_⊙ for the mass of a non-rotating...
BH (Lorenzin & Zampieri 2009). In addition, although the error bars are large, we note that the relation $L_{\text{BH}} \propto kT_{\text{disc}}$ (valid for a standard accretion disc) is compatible with our temperature and luminosity values.

Until now, only a handful of transient ULXs are known and not all of them have been deeply studied. Some examples of ULX transients are M31 ULX-1 and ULX-2 (e.g. Middleton et al. 2012; Esposito et al. 2013; Middleton et al. 2013), three ULXs in the Cartwheel galaxy (Crivellari et al. 2009), CXOU J133705.1-295207 in M83 (Soria et al. 2012), CXOU J132518.2-430304 in NGC 5128 (Sivakoff et al. 2008) and M82 X-1. Their outbursts can be explained, for instance, in terms of an unstable mass transfer from the companion star. The three PULXs – M82 X-2 (e.g. Bachetti et al. 2013), NGC 7793 X-1 (Mutch et al. 2014) and NGC 5907 ULX-1 (e.g. Walton et al. 2015) – from time to time also show high flux variability of several orders of magnitude, which may be explained by the onset/switch-off of the propeller stage. The flux variability of at least a factor of ~40 between high and low flux states of ULX-2 is similar to that ascribed to the propeller effects in M82 X-2 (see e.g. Tsygankov et al. 2016). We did not find any coherent pulsations in ULX-2 with an upper limit on the pulsed fraction of 35%. Only the pulsed fraction of NGC 300 ULX-1 is larger than this value, while the other three PULXs have smaller modulations. Thus, we cannot exclude that ULX-2 hosts a NS accreting at very high rates although, from a spectral point of view, it may be slightly softer than the PULXs (e.g. Pintore et al. 2017; Walton et al. 2018). Furthermore, all the PULXs show super-orbital modulations that the available data do not allow us to see. But a deeper monitoring with Swift or XMM-Newton (during the quiescence of ULX-1) or, even better, with Chandra could provide indications about super-orbital modulations.

The HST image indicates that the source might have an optical counterpart with the colours of an OB type star. Only ~20 ULX optical counterparts have been identified (Tao et al. 2011; Gladstone et al. 2013) and, when individual optical counterparts can be associated with a ULX, they often appear to have the luminosities and colours of OB type giants or supergiants (e.g. Zampieri et al. 2004; Soria et al. 2005), even though the disc emission may contribute significantly to the optical flux (Patruno & Zampieri 2008). New optical observations are strongly needed to constrain the nature of the ULX-2 counterpart.

ACKNOWLEDGEMENTS

We thank Dr. B. Wilkes, Dr. N. Schartel and Dr. Brad Chenko who made the Chandra, XMM-Newton and the Neil Gehrels Swift Observatory DDT observations possible. This work is based on NASA/ESA Hubble Space Telescope observations and obtained from the Hubble Legacy Archive. DJW acknowledges support from STFC in the form of an Ernest Rutherford fellowship.
