(December 27, 2021)

We investigate dynamics of Josephson vortex lattice in layered high Tc superconductors at high magnetic fields. It is shown that the average electric current depends on the lattice structure and is resonantly enhanced when the Josephson frequency matches the frequency of the plasma mode. We find the stability regions of moving lattice. It is shown that a specific lattice structure at given velocity is uniquely selected by the boundary conditions: at small velocities periodic triangular lattice is stable and looses its stability at some critical velocity. At even higher velocities a structure close to a rectangular lattice is restored.

Transport properties of layered superconductors, such as Bi$_2$Sr$_2$CaCu$_2$O$_{8+}$ (BSCCO), in magnetic field parallel the layers are determined by the dynamics of Josephson vortex lattice (JVL). Moving JVL generates travelling electromagnetic wave in the medium. Similar to the Eck resonance in a single junction, one expects a strong resonance emission when the velocity of the lattice matches the plasma wave velocity. In the current-voltage (I-V) dependence this resonance is seen as a strong enhancement of current at fixed voltage. In contrast to a single junction, JVL in layered superconductors has soft degrees of freedom related to the phase shifts between different layers. This leads to a rich variety of dynamic states observed in numerical simulations.

In particular, a periodic lattice corresponds to a constant phase shift between neighboring layers, ranging from 0 for the rectangular lattice to $\pi$ for the static triangular lattice. Moving lattice generates electromagnetic wave with the $c$-axis wave vector selected by the lattice structure. Since the velocity of a plasma wave propagating along the layers depends on this wave vector, the resonant velocity of the lattice depends on its structure.

In this Letter we investigate the stability of moving JVLs and the evolution of structure as a function of its velocity for large size samples. We show that a specific lattice structure at given velocity is uniquely selected by the boundary conditions. At small velocities a periodic triangular lattice is uniquely selected by the lattice structure. At some critical velocity the lattice becomes unstable. At even higher velocities a periodic lattice with the phase shift smaller than $\pi/2$ is restored again.

Consider a layered superconductor in a magnetic field applied along the layers ($y$ axis) with transport current flowing across the layers ($z$ axis). The dynamics of such a system is described by the inductively coupled sine-Gordon equations for the gauge-invariant phase differences $\theta_y$. Introducing the reduced time $\tau = \omega_p t$ and in-plane coordinate $u = x/(\gamma s)$, we express currents $j_x, j_z$, and electric fields $E_{x,n}$ via $\theta_y$ and the reduced magnetic fields $h_n = H_n 2\pi \gamma \lambda_{ab}^2 / \Phi_0$ as

\[
\begin{align*}
  j_{x,n} &= j_J (\sin \theta_n + \nu_{ab} \partial \theta_n / \partial \tau), \\
  j_{x,n+1} - j_{x,n} &= j_J \left( 1 + \nu_{ab} \frac{\partial}{\partial u} \right) \left( \partial \theta_n / \partial u - \frac{h_n}{\mu} \right),
\end{align*}
\]

where $\omega_p$ is the Josephson plasma frequency, $\gamma$ is the anisotropy factor, $s$ is the interlayer spacing, $j_J$ is the Josephson current, $E_p = \Phi_0 \omega_p (2\pi e s)$, $l = \lambda_{ab}/s$, and $j_J \equiv e \Phi_0 / (8\pi \lambda_{ab}^2 \gamma s)$. $\nu_c = 4\pi \sigma_{ab}^2 / (\epsilon c \omega_p)$ and $\nu_{ab} = 4\pi \sigma_{ab} \omega_p / c^2$ are the dissipation parameters, which are determined by the quasiparticle conductivities $\sigma_{ab}$ and $\sigma_{ab}$ and are connected as $\nu_c / \nu_{ab} = \sigma_{ab}^2 / \sigma_{ab}$. Using the above relations we derive from the Maxwell equations the coupled equations for $\theta_y$ and $h_n$

\[
\begin{align*}
  \frac{\partial^2 \theta_n}{\partial \tau^2} + \nu_c \frac{\partial \theta_n}{\partial \tau} + \sin \theta_n - \frac{\partial h_n}{\partial u} &= 0, \\
  \left( \nabla_n^2 - \frac{1}{\tau^2} \right) h_n + \frac{\partial \theta_n}{\partial u} + \nu_{ab} \frac{\partial}{\partial u} \left( \partial \theta_n / \partial u - \frac{h_n}{\mu} \right) &= 0.
\end{align*}
\]

where $\nabla_n^2 h_n \equiv h_{n+1} + h_{n-1} - 2h_n$. Equivalent forms of these equations have been derived in Refs. Taking parameters typical for underdoped BSCCO at $T \approx 50K$: $\gamma = 500$, $\lambda_{ab} = 240$ nm, $s = 15$ Å, $\sigma_{ab} = 2 \cdot 10^4 \Omega \cdot \text{cm}^{-1}$, and $\sigma_c = 2 \cdot 10^{-3} \Omega \cdot \text{cm}^{-1}$, one obtains estimates: $\nu_{ab} \approx 0.1$ and $\nu_c \approx 0.002$, which we will use in numerical computations. For these parameters the dissipation in a wide range of electric and magnetic fields is mainly determined by the in-plane channel.

We consider the situation when all junctions are filled by JVs. This is always the case at high magnetic field $B$ above $\Phi_0 / 5.5 \gamma s^2$ or at high currents, when all junctions are driven into the resistive state. Neglecting self-field of the transport current, we represent a solution to Eqs. (1) and (2) for the resistive state in the form

\[
\begin{align*}
  \theta_y(\tau, u) &= \omega_E \tau + k_H u + \phi_n(\tau) + \tilde{\theta}_n(\tau, u), \\
  h_n(\tau, u) &= h + \tilde{h}_n(\tau, u).
\end{align*}
\]

Here the Josephson frequency $\omega_E$ is determined by the electric field, $\omega_E = E_z / E_p$, and the wave vector $k_H$ is
determined by the magnetic field, \( k_H = 2\pi H\gamma s^2/\Phi_0 = h/2\). \( \theta_n(\tau, u) \) and \( \tilde{\theta}_n(\tau, u) \) are the oscillating phase and magnetic field induced by Josephson coupling, \( \theta_n, \tilde{\theta}_n \propto \sin(\omega_E\tau + k_H u + \alpha_n) \). Solution (3) corresponds to the lattice moving with velocity \( \omega_E/k_H \). The structure of the lattice is determined by the phase shifts \( \tilde{\phi}_n \). Without Josephson coupling the system is degenerate with respect to arbitrary phase shifts \( \tilde{\phi}_n \). Josephson coupling eliminates this degeneracy. It either leads to slow dynamics of phase shifts \( \tilde{\phi}_n \) or selects a certain steady state structure. The equations for \( \tilde{\phi}_n(\tau) \) can be obtained using an expansion with respect to Josephson coupling and averaging over fast degrees of freedom. This procedure will be described in detail elsewhere. [3]

For periodic JVL one has \( \tilde{\phi}_n = \kappa n \). In such a state the chains of JVs in the neighboring layers are shifted by the fraction \( \kappa/2\pi \) of the lattice constant (see inset in Fig. 1). In particular, \( \kappa = 0 \) corresponds to a rectangular lattice, and \( \kappa = \pi \) corresponds to a triangular lattice (ground state at \( \omega_E = 0 \)). In first order with respect to Josephson current, the oscillating phase \( \tilde{\theta}_n \) is given by \( \tilde{\theta}_n = \text{Im} [\mathcal{G}(\kappa) \exp (i(\omega_E\tau + k_H u + \kappa n))] \) with

\[
\mathcal{G}(\kappa) = \left( \frac{\omega_E^2 - i\nu c \omega_E - \frac{k_H^2 (1 + i\nu_{ab}\omega_E)}{2(1 - \cos \kappa) + (1 + i\nu_{ab}\omega_E)^2}}{1} \right)^{-1}.
\]

To second order we obtain the average reduced Josephson current \( i_j \equiv i_j(\kappa, k_H, \omega_E) = \text{Im} \tilde{\theta}_n(\tau, u) \). [11] In the case of not very large in-plane dissipation \( \nu_{ab}\omega_E \ll 2/(1 - \cos \kappa) + 1 \), it has the resonant dependence on the Josephson frequency \( \omega_E \) (electric field)

\[
\mathcal{F}(q, q_1) \equiv \left( -2\omega_E + i\nu c + \frac{ik_H^2\nu_{ab}}{2(1 - \cos q) + \frac{1 + i\nu_{ab}\omega_E}{2}} + \frac{2(1 - \cos q_1)}{2(1 - \cos \kappa) + \frac{1 + i\nu_{ab}\omega_E}{2}} \right) \mathcal{G}(q)\mathcal{G}(q_1).
\]

The lattice is stable if there is no exponentially growing solution in the whole \( q \)-interval, i.e., \( \text{Re}[\alpha(q)] \leq 0 \), for \( 0 \leq q \leq \pi \). The onset of instability is characterized by the wave vector \( q_1 \) of the most unstable mode. There are three special cases: the long-wave instability \( q_1 = 0 \), the short-wave instability \( q_1 = \pi \), and the instability with \( 0 < q_1 < \pi \). One can also distinguish absolute and convective instabilities. [12] The spectrum \( \alpha(q) \) has an important symmetry property \( \alpha(q) = \pi, \kappa = \pi/2 \). This means that a stable region cannot cross the line \( \kappa = \pi/2 \) and it is impossible to evolve continuously from the static triangular lattice to the fastly moving rectangular lattice without intersecting an instability boundary. The triangular lattice always looses its stability before reaching the resonance \( \omega_E = k_H/2 \), at the frequency \( \omega_\Delta(k_H) \) which is determined by a simple analytical equation

\[
\omega_\Delta^2 - \frac{k_H^2}{4} = -\omega_\Delta \left( \nu c + \frac{k_H^2
u_{ab}}{4} \right) \left( \sqrt{1 + \nu_{ab}\omega_\Delta^2} - \nu_{ab}\omega_\Delta \right).
\]

To explore the stability of JVL we calculated numerically \( \text{Re}[\alpha(q)] \) throughout the \( \omega_E - \kappa \) plane and found the lines at which either \( \text{Re}[\alpha(q)] = 0 \) at finite \( q \) or \( \text{Re}[d^2\alpha(q)/dq^2] = 0 \) at \( q = 0 \). The stability diagram for representative parameters \( \nu c = 0.002, \nu_{ab} = 0.1 \), and \( k_H = 8 \) is shown in Fig. 3. For these parameters we found three stability regions at moderate \( \omega_E \): (i) the low-velocity region located below the resonance line and at \( \pi/2 < \kappa < \pi \), (ii) the high-velocity region located along the resonance line with \( \kappa \) approaching 0 with increase of \( \omega_E \), and (iii) the region located above the resonance line and at \( \pi/2 < \kappa < \pi \) (this region disappears at higher fields). At the boundary of the first region the lattice experiences a long-wave instability for \( \kappa > 2.04 \). At smaller \( \kappa \) the instability occurs at finite wave vector \( q = q_1 \) and \( q_1 \) grows continuously with decrease of \( \kappa \).

Selection by the system of a specific wave number \( \kappa \) from the continuous spectrum is not directly related to stability of the corresponding periodic structure. For the static case the structure is selected by the minimum energy condition. Such a condition is absent in the dynamic
case. In this case a specific JVL structure can be determined by the boundary. To demonstrate this, we consider a semi-infinite stack of junctions with \( n = 1, 2, \ldots \) separated by a sharp boundary from the medium with arbitrary electromagnetic properties. To derive equations for the phase shifts \( \phi_n \) for such system we have to find a solution of the linear equations without Josephson coupling taking into account the boundary conditions. For plasma wave with given frequency \( \omega = \omega_E \) and wave vector along the layers \( k = k_y \) the oscillating phases (\( \theta_n \)) and magnetic fields (\( h_n \)) in the junctions can be written as

\[
\theta_n, h_n \propto \exp(-iq_+n) + B \exp(iq_+n), \text{ at } n \geq 1
\]

where \( q_+ = q_+(k, \omega) \) (complex) wave vector given by

\[
\cos q_+ = 1 - \frac{k^2 (1 + i\nu_{ab}\omega)}{2(\omega^2 - i\nu_{c}\omega)} + \frac{1 + i\nu_{ab}\omega}{2i},
\]

with \( \text{Im}[q_+] > 0 \). The properties of the boundary are completely characterized by the complex amplitude of reflected wave \( B \equiv B(k, \omega) \), which has to be found by matching the solution \( [7] \) with electromagnetic oscillations in the medium at \( z < 0 \). In general, \( B(k, \omega) \) can be a complex number with arbitrary absolute value. Only in the simplest case of vanishing dissipation and propagating wave \( \text{Im}[q_+] = 0 \), \( B(k, \omega) \) determines a conventional reflection coefficient, \( R(k, \omega) = |B(k, \omega)|^2 \), and has property \( |B(k, \omega)| < 1 \). A large class of boundaries, including boundary with free space, is well described by the ideal reflection \( B = -1 \). Averaging with respect to oscillating phases and field we derive the following equation for the steady state phase shifts \( \phi_n \)

\[
\frac{1}{2} \sum_{m=1}^{\infty} \text{Im} [G(n, m) \exp(-i(\phi_n - \phi_m))] = iJ,
\]

where

\[
G(n, m) = G_0(n - m) + B G_0(n + m), \quad G_0(n) = G_0(n; k_H, \omega_E) = \frac{\delta_n}{\omega^2_E - i\nu_c \omega_E} - \frac{k^2_H (1 + i\nu_{ab}\omega_E) \exp iq_+ |n|}{(\omega^2 - i\nu_c \omega_E)^2 \frac{2i}{q_+}},
\]

The second term in Eq. \( [10] \) describes the surface contribution and vanishes at \( n, m \rightarrow \infty \). The solution, corresponding to the lattice in the bulk, has the form \( \phi_n = \kappa n + u_n \), where \( u_n \) is the surface deformation, \( u_n \rightarrow 0 \) at \( n \rightarrow \infty \). Substituting this ansatz into Eq. \( [10] \) we obtain a nonlinear degenerate system of equations for \( u_n \). The solution for \( u_n \) exists only for special values of \( \kappa \), i.e., the bulk structure is selected by the boundary conditions. For such selected states \( z \) component of the Poynting vector \( P_z \) is always directed from the boundary towards the bulk of the sample. \( [11] \) A similar pattern selection mechanism is relevant for various nonequilibrium systems. \( [11] \) At small \( \omega_E \) the system becomes linear with respect to \( u_n \) and its solvability condition can be found analytically. In the case \( B = -1 \) we obtain deformation of the lattice at small velocities \( \kappa \approx \pi - (\nu_{ab} + 7\nu_c/k_H^2) \omega_E \). In finite system with identical boundaries the configuration is typically symmetric because each boundary selects the same wave number. The waves collide in the middle forming a phase defect. \( [17] \)

To find the steady state configurations at all velocities we solved Eq. \( [8] \) numerically taking \( B = -1 \) and using the same parameters \( (\nu_c = 0.002, \nu_{ab} = 0.1) \). The dependence \( \kappa(\omega_E) \) obtained from these solutions for \( k_H = 8 \) is shown in Fig. \( [10] \) together with the stability regions. At small velocities the lattice experiences smooth evolution of structure with the lattice wave vector \( \kappa \) decreasing from \( \pi \) at zero velocity to smaller values until it hits the instability boundary. At higher velocities the stable lattice with \( \kappa < \pi/2 \) is restored. The structure continues to evolve smoothly towards the rectangular configurations with increase of velocity. Near the line \( \kappa = \pi/2 \) we observe transition to the double-periodic lattice \( \phi_n = \pi n/2 + (-1)^n v \), which becomes stable at high fields.

Fig. \( [10] \) shows evolution of the current-voltage dependence and the in-plane Poynting vector \( [8] \) with increase of magnetic field. Up to magnetic field \( H \approx \sqrt{\sigma_{ab}/(\gamma^2 \sigma_c)} \phi_0/(\pi \gamma s^2) \) \( (k_H \approx 16) \), the current-voltage dependencies have two stable branches, corresponding to moving periodic lattices, separated by broad instability region where periodic JVL can not exist. In this regime two lattice solutions exist within a finite range of currents. Such coexistence is facilitated by the high in-plane dissipation, which causes strong dependence of the JVL velocity on its structure. Within the coexistence region one can expect a family of intermediate states, in which the system is split into two (or more) domains moving with different velocities separated by a phase defect (dynamic phase separation, see Fig. \( [10] \)). The phase-separated states give the most natural interpretation of the multiple I-V branches observed by Hechtfischer \( et \, al. \), who studied transport properties of JVL in BSCCO mesas at high magnetic fields. \( [16] \) This interpretation can be verified by measuring the spectrum of microwave irradiation emitting by the stack. Instead of a single peak located at the Josephson frequency corresponding to the average voltage, the spectrum of irradiation should contain two peaks corresponding to the “fast” and “slow” states.

In conclusion, we investigated stability and boundary structure selection of the driven JVL. We found two major stability regions, separated by unstable region: the low-velocity region correspondsto moving structure close to triangular lattice and the high-velocity region corresponds to an almost rectangular lattice.

AEK thanks R. Kleiner, N. F. Pedersen, M. Tachiki, and K.Gray for helpful discussions. This work was supported by the U.S. DOE, Office of Science under contract...
FIG. 1. Stability regions of moving Josephson lattice in the plane \( \omega_E - \kappa \) calculated for representative parameters \( \nu_c = 0.002, \gamma_{ab} = 0.1, \) and \( k_H = 8 \). Grey regions correspond to unstable lattices. Sections of the boundaries marked by black correspond to the long-wave instability. Sections marked by light grey correspond to the instability with \( q = \pi \). Line starting at \((0, \pi)\) shows dependence of the lattice wave vector on the frequency \( \omega_E \) selected by the boundary with free space. We also show the resonance line, corresponding to matching between the Josephson frequency and the frequency of the plasma wave at the wave vector \( \kappa \). Inset sketches a steady state corresponding to a regular lattice.

FIG. 2. (a) Current-voltage characteristics at different magnetic fields, for \( k_H = 6, 8, 12, \) and 16 (for \( \gamma = 500 H \approx k_H \cdot 0.3T \)). The dependencies are obtained using numerically computed steady states with parameters \( \nu_c = 0.002, \nu_{ab} = 0.1 \). Thick lines show stable branches and thin lines show unstable branches. The branches, marked by dashes, correspond to the double-periodic lattices. (b) Electric field dependencies of the Poynting vector along the layers for electromagnetic wave generated by the moving lattice (see Eq. (b)). The scale \( P_{ab} \) is defined in Eq. (b).

FIG. 3. Multibranch structure of the current-voltage characteristic due to dynamic phase separation. Two states corresponding to slow lattice motion (velocity \( \nu_s \)) and fast lattice motion (velocity \( \nu_f \)) coexist within the current range marked at the vertical axis. In this region the intermediate phase-separated states exist, in which the system is split into fastly and slowly moving regions. The intermediate branch corresponding to one of such states is shown by dotted line.
