Histopathological examination of congenital corneal staphyloma and prognosis after penetrating keratoplasty

Yu Wan, MD, Gege Xiao, MD, Ting Yu, MD, Pei Zhang, MD, Jing Hong, MD, PhD*

Abstract
The aim of this study was to investigate the histopathological manifestations of congenital corneal staphyloma accompanied by anterior segment dysgenesis and evaluate the prognosis after penetrating keratoplasty with an ultralarge button graft.

We retrospectively studied 8 pediatric patients with large congenital corneal staphylomas in the Department of Ophthalmology of Peking University Third Hospital, China, between September 2014 and December 2018. All patients underwent penetrating keratoplasty with ultralarge button grafts, as well as additional operations according to the abnormality of each eye. Pathological investigations of all samples obtained during penetrating keratoplasty were performed with hematoxylin and eosin staining.

The main clinical characteristic of congenital corneal staphyloma was an extremely opaque and ectatic cornea. Histopathological examination showed abnormal corneal epithelia and stroma and an absence of Bowman membrane, Descemet membrane, and the endothelium. Different severities of anterior segment dysgenesis, presenting as various histopathological manifestations, were observed in all cases. Several postoperative complications occurred after penetrating keratoplasty in some of the patients; however, the complications were discovered and treated accordingly in a timely manner. Six patients achieved good visual outcomes and a satisfactory cosmetic appearance after penetrating keratoplasty. One patient eventually lost the transparency of the button because of corneal neovascularization, and 1 patient lost visual function because of retinal detachment.

Congenital corneal staphyloma combined with anterior segment dysgenesis can exhibit various manifestations on histopathological examination. Penetrating keratoplasty with an ultralarge button graft seems to be a suitable treatment for congenital corneal staphyloma to obtain good functional and aesthetic prognoses.

Keywords: anterior segment dysgenesis, congenital corneal staphyloma, histopathological manifestations, penetrating keratoplasty, ultralarge button graft

1. Introduction
The protrusion of an opaque cornea at birth is a very rare condition. Previous studies have suggested that the prevalence of congenital corneal opacities ranges from 3/100,000 to 6/100,000 newborns. Congenital corneal staphylomas may account for approximately 11% of congenital corneal opacities. Although the incidence is rare, congenital corneal staphyloma is a lifelong vision-threatening disease associated with a poor visual prognosis and a seriously altered facial appearance.

The clinical features of congenital corneal staphyloma include severe corneal opacification and anterior corneal protrusion. The anterior segment of the involved eye is usually anomalous. Typical histopathological manifestations of congenital corneal staphyloma include the absences of Bowman membrane, Descemet membrane, and the endothelium. The iris is usually atrophic and adherent to the posterior surface of the cornea. However, some congenital corneal staphylomas present with anterior segment dysgenesis, which exhibits various histopathological manifestations. This combination of disorders increases the difficulty of establishing an accurate diagnosis and early treatment regimen. Due to the extremely rare incidence of large congenital corneal staphylomas combined with anterior segment dysgenesis, very few studies have illustrated the various histopathological manifestations in detail.

Currently, there lacks a universally recognized treatment for congenital corneal staphyloma. The fates of most eyes are evisceration or enucleation. However, the psychological trauma and the physical disability caused by evisceration or...
enucleation are quite extreme.\textsuperscript{10–12} Penetrating keratoplasty for mild forms of congenital corneal staphyloma has been reported to improve the functional and esthetic prognosis\textsuperscript{13,14} but in severe cases, the incidence of graft failure is high.\textsuperscript{15,16} Thus, successful therapeutic practices and proper surgical design are of great importance to determine an optimal treatment and enhance prognosis.

In this study, we present the various histopathological manifestations of large congenital corneal staphylomas combined with anterior segment dysgenesis. We further evaluate the prognoses after penetrating keratoplasty with ultralarge button grafts.

2. Materials and methods

2.1. Patients

We retrospectively studied 8 pediatric patients with congenital corneal staphylomas at Peking University Third Hospital, Peking University Eye Center, between September 2014 and December 2018. The cohort included 6 boys and 2 girls, aged 3 months to 1 year. This investigation was approved by the Institutional Review Board of Peking University Third Hospital, and informed consent was obtained from the representatives of all patients.

2.2. Examination and surgery

All patients underwent basic ocular examinations including visual acuity (if possible), intraocular pressure (IOP), exophthalmos, eye position and eye movement evaluations. The structure of the anterior segment was observed with a slit-lamp examination and, when possible, ultrasound biomicroscopy (UBM) and anterior segment optical coherence tomography (AS-OCT). The posterior segments were evaluated by a B-type ultrasound scan. Systemic examination and biochemistry tests were conducted to identify other systemic diseases. All of the patients underwent penetrating keratoplasty under general anesthesia. Additional operations, such as iridectomy, lens extraction, anterior vitrectomy, goniosynechialysis, and gonioplasty, were also conducted according to the abnormality of each eye.

2.3. Histopathological examination

The excised corneal tissues were sent for histopathological examination. The sections were stained with hematoxylin and eosin (HE), and then examined by light microscopy.

2.4. Postoperative follow-up

All 8 patients received close observation and attentive nursing care postoperatively. Antibiotics, corticosteroid, immunosuppressant, and artificial tears were topically used after surgery. No systemic immunosuppressive therapy was applied. In addition, specific therapies were conducted according to different postoperative complications. The follow-up period ranged from 4 months to 4 years. The follow-up frequency ranged from 1 week to 6 months. Prognostic evaluations included visual acuity, IOP, corneal state, and intraocular condition.

3. Results

Eight eyes with congenital corneal staphyloma were retrospectively studied (Table 1). The mean age of the patients was 7 months and ranged from 5 months to 1 year. In all patients, the protruding opaque mass on the eye was present at birth. Most of the patients presented no systemic disease or other congenital defects, except for 1 patient who had polydactyly of the right hand as well as a urethral cleft. All of the patients were treated by penetrating keratoplasty with ultralarge button grafts. The follow-up period ranged from 4 months to 4 years (mean, 1.7 years).

3.1. Clinical observation

On ocular examination, all the patients exhibited a protruding opaque mass on the cornea (Fig. 1). Two were skin-like, 3 were staphylomatous, and the other 3 were leukomatous (Table 1). The UBM and AS-OCT showed an opaque and thickened cornea. The iris was adhered to the posterior surface of cornea (Fig. 1). The anterior chamber depth was reduced or normal, varying by the severity of each dysgenesis. The B-mode ultrasound scan showed normal posterior segments.

3.2. Penetrating keratoplasty and intraoperative conditions

All patients underwent penetrating keratoplasty with an ultralarge donor corneal/corneoscleral button. To remove the lesions thoroughly, all masses were excised together with 1 mm peripheral normal cornea. After excising the corneal mass, the abnormal anterior segments with varying severities were exposed, and additional operations were conducted depending on the abnormality in each eye (Table 1). Iridectomy was conducted in case the iris was abnormal and tightly adhered to the posterior surface of the cornea. If there were some remnants of healthy iris, the normal iris was carefully separated and preserved as much as possible. Anterior vitrectomy was conducted in patients with severe anterior segment dysgenesis, to avoid postoperative complications such as vitreous hernia and intraocular hypertension. The lens was extracted if it was opaque, degenerated, or tightly attached to the posterior surface of the cornea. Goniosynechialysis and gonioplasty were also conducted in some cases when necessary, according to each specific situation.

3.3. Histopathological examination

Postoperatively, the excised tissue was sent for histopathological examination (Fig. 2). Histopathology with HE staining revealed abnormal corneal epithelia and stroma. Bowman membrane, Descemet membrane, and the endothelium were absent. Anterior segment dysgenesis was observed in all patients, but the histopathological manifestations varied (Table 2).

3.4. Postoperative complications and prognosis

Three patients recovered well after surgery and showed no postoperative complications. Postoperative complications occurred in 5 patients but were discovered and treated in a timely manner (Table 1). Epithelial defects occurred in 4 eyes. Two were identified half a month after surgery, one was identified half a year after surgery, and the other was identified 1 year after surgery. For children with persistent epithelial defects, temporary eyelid sutures for an average period of 3 months were conducted, and achieved a good effect in corneal epithelial defects healing. Eyelid sutures were only conducted at the inner and outer canthus to reduce the exposure area; meanwhile, the sight could still pass...

stroma is disorganized, vascularized, and hypercellular. Eyes all show keratinization secondary to exposure. The cornea adhered to its posterior surface. The epithelium is intact but may ylomas include corneal ectasia, with remnants of an atrophic iris the histopathological characteristics of congenital corneal staph- atypical leukomatous or skin-like appearance. Microscopically, a severely opaque and protruding cornea. In our study, the 8 features, and analyzed the prognosis after penetrating kerato- results in a poor prognosis with low visual function. Because of the irises with atrophic or normal cornea to ensure the developmental stages will lead to various manifestations. In this study, all 8 patients accepted penetrating keratoplasty with ultralarge button grafts. Six patients achieved a satisfactory cosmetic appearance and good visual outcomes. Here, we recommend penetrating keratoplasty as an early treatment for congenital corneal staphyloma. Delayed intervention may result in dramatic growth of the abnormal tissue, abnormal ocular development, or even spontaneous phthisis bulbi. In addition, the corneal opacity may influence the normal development of vision and lead to amblyopia. As for the surgical procedures of penetrating keratoplasty, we thought there were several tips crucial for the postoperative prognosis of this disease. First, the degree of lens involvement, the anterior chamber depth, and the existence of other ocular abnormalities varied among patients. The pathogenesis of congenital corneal staphyloma may partly explain this phenomenon. Congenital corneal staphyloma is presumed to be caused by the failure of the normal migration of neural crest cells. During the fifth to sixth week of gestation, separation of the lens vesicle and basement membrane of the surface ectoderm occurs, followed by 3 successive developmental stages. The first stage gives rise to the corneal endothelium and trabecular meshwork, the second stage gives rise to the corneal keratinocytes and corneal stroma, and the third stage produces the iris. The arrest of any of these developmental stages will induce anterior segment dysgenesis, and arrest of different developmental stages will lead to various manifestations.

4. Discussion

Congenital anterior staphyloma is a developmental abnormality characterized by an opaque and protruding cornea and usually results in a poor prognosis with low visual function. Because of its rarity, there are few studies on congenital anterior staphylomas, and the understanding of this disease is still limited. In the present study, we retrospectively studied 8 cases of congenital corneal staphyloma, described the histopathological features, and analyzed the prognosis after penetrating keratoplasty with an ultralarge button graft.

The typical clinical feature of congenital corneal staphyloma is a severely opaque and protruding cornea. In our study, the 8 eyes all fit the clinical features of congenital corneal staphyloma. Three were typically staphyloma-like, and the others had an atypical leukomatous or skin-like appearance. Microscopically, the histopathological characteristics of congenital corneal staphylomas include corneal ectasia, with remnants of an atrophic iris adhered to its posterior surface. The epithelium is intact but may show keratinization secondary to exposure. The corneal stroma is disorganized, vascularized, and hypercellular. Bowman membrane, Descemet membrane, and the endothelium are usually absent. Similar corneal histopathological features were found in our cases, but the manifestations of anterior segment dysgenesis varied. The severity of iris dysplasia, the degree of lens involvement, the anterior chamber depth, and the existence of other ocular abnormalities varied among patients. The pathogenesis of congenital corneal staphyloma may partly explain this phenomenon. Congenital corneal staphyloma is presumed to be caused by the failure of the normal migration of neural crest cells. During the fifth to sixth week of gestation, separation of the lens vesicle and basement membrane of the surface ectoderm occurs, followed by 3 successive developmental stages. The first stage gives rise to the corneal endothelium and trabecular meshwork, the second stage gives rise to the corneal keratinocytes and corneal stroma, and the third stage produces the iris. The arrest of any of these developmental stages will induce anterior segment dysgenesis, and arrest of different developmental stages will lead to various manifestations.

In this study, all 8 patients accepted penetrating keratoplasty with ultralarge button grafts. Six patients achieved a satisfactory cosmetic appearance and good visual outcomes. Here, we recommend penetrating keratoplasty as an early treatment for congenital corneal staphyloma. Delayed intervention may result in dramatic growth of the abnormal tissue, abnormal ocular development, or even spontaneous phthisis bulbi. In addition, the corneal opacity may influence the normal development of vision and lead to amblyopia. As for the surgical procedures of penetrating keratoplasty, we thought there were several tips crucial for the postoperative prognosis of this disease. First, the lesions should be removed thoroughly. We resected the masses together with a little peripheral normal cornea to ensure the effect. Moreover, for the cases with severe anterior segment dysgenesis, thorough anterior vitrectomy is important to avoid postoperative complications such as vitreous hernia and intraocular hypertension. The abnormal iris should be excised; meanwhile, the healthy remnants should be preserved as much as possible. Complete separation of the anterior chamber angle is also important.

Several postoperative complications occurred in our patients, similar to previous reports. One complication was ocular hypertension, which is considered to be a common clinical occurrence after penetrating keratoplasty. Several factors
were considered contributing factors to postoperative ocular hypertension in our cases, such as severe congenital anterior segment dysgenesis, additional surgeries combined with penetrating keratoplasty, surgical injuries to the anterior chamber angle when excising abnormal tissues and postoperative inflammation. Another postoperative complication was corneal epithelial defects, which was also frequently occur in the donor cornea after penetrating keratoplasty.\textsuperscript{[23]} Contributing factors for postoperative epithelial defects are considered to be ocular surface disorders, exposure secondary to eyelid abnormality, ocular cicatrizing disorders and limbal stem cell deficiency.\textsuperscript{[24]} Because most of our patients underwent penetrating keratoplasty

Figure 2. Histopathological manifestations of congenital corneal staphyloma (HE staining). (A) The whole cornea scanning image of the staphyloma. The corneal tissue was thickened and had a rough surface. (B, C) The corneal stroma was thickened and presented connective tissue-like changes. The dysplastic iris adhered to the posterior surface of the cornea (black arrows). Irregular collagen fibrils, fibroblast-like cells, and various blood vessels (red arrows) were observed. (D) The corneal epithelium was hyperplastic, with squamous metaplasia (blue arrows). Bowman membrane was absent. (E) The dysplastic lens tissue was embedded in the cornea (purple arrow). Descemet membrane and the endothelium were absent.
with ultralarge button grafts to replace the diffusely diseased corneas, little or no host endothelial cells were preserved after surgery. The deficiency of limbal stem cells was considered the main contributing factor for postoperative epithelial defects in our cases. Additionally, one patient lost visual function because of retinal detachment three months postoperatively. This patient had the most severe degree of ocular dysgenesis among the 8 cases; no normal corneal tissue, corneal limbus tissue, iris tissue or lens tissue was found in this eye. Severe dysgenesis and complicated surgical procedures were considered contributing

| 7   | Squamous metaplasia, with localized keratin formation                     | Fusiform fibroblast-like cell hyperplasia and various blood vessels |                                                                        |                   |             | / |
| 8   | Epidermoid hyperplasia                                                    | Blood vessels, focal degenerative lens tissue in deep region          |                                                                        |                   |             | / |
factors for her retinal detachment. Moreover, atypical hyperplasia was found in this eye after surgery, and this might also have contributed to the eye dysfunction. Due to special ocular features and a more active immune system, penetrating keratoplasty in children has a higher graft failure rate than penetrating keratoplasty in adults. It has been reported that graft survival in children under 5 years old is <40% at 16 years postoperatively. In addition to age, congenital structural abnormalities of the anterior segments also markedly reduce the visual outcome after corneal transplantation. Moreover, additional noncorneal surgical procedures, such as lenectomy and vitrectomy, at the time of penetrating keratoplasty are associated with graft failure in children. In addition, the use of ultralarge button grafts for penetrating keratoplasty increased the risk for graft failure. It has been reported that a large donor cornea increases the risk of graft rejection since there is a higher number of dendritic Langerhans cells in the limbal region of the cornea than in the center. Furthermore, a large donor cornea is positioned relatively close to the limbal region and is therefore exposed to the antigen/antibody influences of the limbal vasculature. In brief, our 8 cases of congenital corneal staphyloma combined with anterior segment dysgenesis exhibited various histopathological manifestations. These histopathological findings may provide clues for the recognition of this disease and help to enhance the understanding of rare abnormalities. Although the risk of postoperative complications is high in young children and severe cases, satisfactory outcomes were obtained in most of our cases after penetrating keratoplasty with an ultralarge button graft. Therefore, early surgical treatment is still recommended as a priority option to obtain better development of the orbit and vision. For patients whose limbal stem cells are diffusely affected, the difficulty in corneal epithelial regeneration after transplantation is still a notable problem. Concurrent surgical procedures at the time of penetrating keratoplasty had a detrimental effect on graft survival, but they were necessary and ineluctable for patients who had multiple ocular abnormalities. A better understanding and management of these factors may improve the prognosis in the future.
