A Role for G-Proteins in Directing G-Protein-Coupled Receptor–Caveolae Localization

Rhodora Cristina Calizo and Suzanne Scarlata*

Department of Physiology and Biophysics, Stony Brook University, Stony Brook, New York 11794-8661, United States

ABSTRACT: Caveolae are membrane domains that may influence cell signaling by sequestering specific proteins such as G-protein-coupled receptors (GPCRs). While previous reports largely show that $\alpha_q$ subunits, but not other G-proteins, interact strongly with the caveole protein, Caveolin-1 (Cav1), the inclusion of GPCRs in caveolae is controversial. Here, we have used fluorescence methods to determine the effect of caveolae on the physical and functional properties of two GPCRs that have been reported to reside in caveolae, bradykinin receptor type 2 (B$_2$R), which is coupled to $\alpha_q$, and the $\mu$-opioid receptor (μOR), which is coupled to $\alpha_i$. While caveolae do not affect cAMP signals mediated by μOR, they prolong Ca$^{2+}$ signals mediated by B$_2$R. In A10 cells that endogenously express B$_2$R and Cav1, downregulation of Cav1 ablates the prolonged recovery seen upon bradykinin stimulation in accord with the idea that the presence of caveolae prolongs $\alpha_q$ activation. Immuno fluorescence and Förster resonance energy transfer (FRET) studies show that a significant fraction of B$_2$R resides at or close to caveolae domains while none or very little μOR resides in caveolae domains. The level of FRET between B$_2$R and caveolae is reduced by downregulation of $\alpha_q$ or by addition of a peptide that interferes with $\alpha_q$–Caveolin-1 interactions, suggesting that $\alpha_q$ promotes localization of B$_2$R to caveolae domains. Our results lead to the suggestion that $\alpha_q$ can localize its associated receptors to caveolae domains to enhance their signals.

More than 50 years ago, electron micrographs of the plasma membrane of cells revealed dense invaginations of 50–100 nm that were named caveolae (little caves). Caveolae were found to be present in almost all differentiated mammalian cells and are composed of the proteins Caveolin-1 (Cav1) or the muscle specific Caveolin-3 (Cav3), Caveolin-2 (Cav2), and numerous other proteins (see refs 1–3). Many proteins that reside in caveolae are involved in cell signaling, which has led to the speculation that caveolae may be involved in the organization of signaling domains (see refs 4–9). If related signaling proteins localize in caveolae, then these domains could facilitate rapid and directed signals. However, it is unclear whether various signaling proteins localize in caveolae domains because results from immunofluorescence and fractionation studies appear to be contradictory.

An important class of signaling proteins that may target caveolae consists of G-protein-coupled receptors (GPCRs). GPCR signaling occurs through a series of sequential molecular interactions that begin with the binding of an extracellular agonist. This binding is transmitted to downstream effectors in the cytoplasm through activation of heterotrimeric G-proteins. Many GPCRs and G-protein subunits appear to localize to caveolae domains (see refs 10, 12, and 13). Some recent studies of live cells have indicated that components involved in G-protein signaling reside in preformed signaling complexes (e.g., refs 14 and 15) and that Cav1 can alter their interactions by specifically binding to one or more components. Thus, caveolae domains may play a necessary and significant part in GPCR signaling by mediating GPCR oligomerization, their association with agonists, and their interaction with intracellular G-proteins.

Previous studies have suggested that $\alpha_q$ subunits reside in caveolae domains whereas $\alpha_o$, $\alpha_g$, and $\gamma$ subunits prefer non-caveolae domains. Our laboratory used live cell fluorescence imaging and correlation spectroscopy to show that in the basal state $\alpha_q$ and $\gamma$ localize to caveolae domains. Activation of $\alpha_q$ strengthens its interaction with Cav1, promoting the release of $\gamma$ subunits from caveolae domains and extending the time of $\alpha_q$ activation. This stabilization of activated $\alpha_q$ through its interaction with Cav1 is seen by a prolonged calcium response that is thought to be due to a combination of stabilization of the activated state of $\alpha_q$ by Cav1 and the extended time for $\gamma$ recombination. This change in the duration of $\alpha_q$-mediated signals does not appear to be the case for other $\alpha$ families.

In this study, we determined whether the presence of caveolae can alter the function and dynamics of two class A GPCRs, the $\mu$-opioid receptor (μOR), which is coupled to $\alpha_i$, subunits, and the bradykinin type 2 receptor (B$_2$R), which is coupled to $\alpha_q$ subunits. Both receptors have been reported to localize in caveolae (see below). We studied these receptors mainly in Fisher rat thyroid (FRTwt) cells, which do not express detectable levels of Cav1, and a sister cell line that is stably transfected with canine Cav1 (FRTCav+) and displays
caveolae domains. Additionally, FRT cells do not have endogenous μOR or B2R receptors, the contribution of which could complicate the analysis of FRET measurements and functional assays.

μOR binds morphine and is a target of many analgesics, including opiates (see ref 20). μOR activates Gαi resulting in inhibition of adenylate cyclase and a decrease in the level of cellular cAMP. Co-immunoprecipitation studies suggest that μOR localizes to lipid rafts and has been shown to be localized in Cav3 microdomains in adult cardiomyocytes. Although caveolin expression has not been fully elucidated in the nervous system where μOR is most abundant, it is upregulated in aging brains and its downregulation induces demyelination of neurons. These observations imply that Cav1 may be indirectly involved in promoting changes in plasticity, neuroprotection, neurodegeneration, and aging.

B2R is a key mediator of the inflammation response. B2R signals through Gαi, resulting in the activation of phospholipase Cβ (PLCβ) resulting in an increase in the level of intracellular calcium and activation of protein kinase C. Unlike B1R, which is expressed only during inflammation, B2R is expressed continuously, although its tissue expression is limited. We have previously found that in the presence of caveolae, activation of Gαi by muscarinic receptors results in prolonged calcium responses due to sustained activation of Gαi by Cav1. Thus, caveolae may promote inflammatory responses through sustained and synergistic B2R signaling.

Here, we have used fluorescence methods to study μOR and B2R. The use of fluorescence methods allows us to conduct real-time measurements of receptor localization and dynamics in intact cells, thereby eliminating problems associated with cell disruption. We find that the function and localization of μOR are largely unaffected by caveolae. Alternately, B2R→Gαi signaling is impacted by caveolae, even though the receptors do not appear to significantly penetrate into these domains. Our FRET studies suggest that receptors do not directly localize to caveolae but require Gαi to scaffold them to these domains.

## MATERIALS AND METHODS

**Materials.** FRTwt and FRTcav+ cells and canine Caveolin-1-eGFP DNA were gifts from D. Brown (Stony Brook University). μOR-eYFP, μOR-eCFP, and Gαi-eYFP were from L. Devi (Mount Sinai Medical Center, New York, NY). Gαi-eYFP and Gαi-eGFP were from C. Berlot (Geisinger Research). B2R and B2R-GFP were from F. Leeb-Lundberg (University of Texas Health Science Center). The plasmid of eCFP and eYFP linked by a 12-amino acid peptide chain as a positive control for FRET experiments was from J. Pessin (Albert Einstein College of Medicine, Bronx, NY). mCherry-Cav1, eYFP-Cav1, and eCFP-Cav1 were constructed as described from canine Cav1-eGFP by excising it as a XhoI and BamHI fragment and subcloning it into the same sites in pmcherry-C1, pEYFP-C1, and pECFP-C1 (Clontech). Sequencing of all these plasmids showed an in-frame fusion of pmcherry, eYFP, or eCFP at the N-terminus of Cav1 and a six-amino acid linker (SGSRAA) between the Cav1 and fluorophore constructs.

**Cell Culture and Transfection.** FRTwt and FRTcav+ cells have been described previously as rat aortic smooth muscle cells (A10 cells). Expression of Cav1 in A10 cells was downregulated by treating the cells with siRNA (Cav1) from Dharmaco, Inc., according to the manufacturer’s instructions.

The efficiency of downregulation was determined by immunofluorescence using the anti-Cav1 antibody bound to Alexa 647-conjugated secondary antibody in which the fluorescence intensities per cell of wild-type A10 cells (n = 11; 43 ± 13%) versus the Cav1 knockdown (n = 17; 21 ± 7%) cells were obtained and compared. These measurements showed a Cav1 knockdown efficiency of approximately 51%. Western blot analyses were performed to compare receptor expression levels and were conducted using the reagents and antibodies described in refs 16 and 17.

The levels of expression of Cav1 in FRTcav cells and in transfected HEK293 cells were found to be similar to the endogenous level of expression of Cav1 in NIH3T3, A10, and MDA MB-231 cells by Western blotting. Additionally, B2R expression levels in transfected FRT cells were found to be similar to endogenous levels in NIH3T3 cells and A10 cells. Similar expression levels of cells transiently transfected with B2R and cells endogenously expressing B2R (NIH3T3 and A10 cells) correlate with the comparable extents of calcium release upon stimulation with bradykinin.

**FRET Spectroscopy of Membrane Fractions.** Approximately 3 × 10^7 cells expressing B2R-eYFP, μOR-eYFP, or eCFP-Cav1 were homogenized in ice-cold lysis buffer (250 mM sucrose, 20 mM HEPES (pH 7.4), 1.5 mM MgCl2, 1 mM EDTA, 1 mM EGTA, protease inhibitor cocktail, 1% Triton X, 0.5% NP-40, and 1 mM DTT). The membrane fractions were collected by centrifugation at 50000g for 1 h at 4 °C. The concentrations of B2R-eYFP and eCFP-Cav1 were found to be 0.12 and 0.30 μM, respectively, by Western blot analysis. Expression and purification of recombinant Gαi and Gαi through baculovirus infections of Sf9 cells have been described previously. Gαi and Gαi were activated by incubation in 1 mM GDP/βS in 50 mM HEPES, 100 mM NaCl, 4 mM MgCl2, 1 mM DTT, and 50 mM (NH4)2SO4 for 1 h at 30 °C. B2R-eYFP (5 nM) and eCFP-Cav1 (10 nM) were titrated with purified Gαi and Gαi. FRET measurements between B2R-eYFP or μOR-eYFP and eCFP-Cav1 were performed by monitoring the increase in the emission of eYFP (560 nm) upon excitation of eCFP (450 nm) and normalized using the intensities of eYFP emission upon eYFP excitation.

**Ca2+ Measurements.** Intracellular Ca2+ levels in cells transiently transfected with B2R or μOR were harvested and incubated with 1 μM Fura 2-AM in Hanks Balanced Salt Solution (HBSS, Gibco) with 1% BSA. Cells (1 × 10^7) were incubated with 1 μM Fura 2-AM for 30 min, pelleted, washed twice with HBSS, and incubated for an additional 15 min for de-esterification of Fura 2-AM. Fluorescence measurements were taken as described in ref 17.

Calcium changes in adherent cells were measured using 5 μM Calcium Green, or Calcium Orange if the cells were already expressing a GFP-labeled receptor, on a Zeiss Confocor II instrument as previously described.

**Intracellular CAMP Measurements.** μOR-expressing cells were serum-starved and pretreated with 1 mM 3-isobutyl-1-methylxanthine (IBMX) and stimulated with morphine in the presence of 10 μM forskolin. The assay was stopped with 1% perchloric acid and incubated for 1 h. Cyclic AMP was measured from the supernatant using a[^3]H]cAMP assay kit (GE Healthcare) following the manufacturer’s instructions. Inhibition of cAMP by morphine is expressed as the percent forskolin activation in the absence of agonist.

**Colocalization Studies.** FRTcav+ cells transfected with μOR-eGFP or B2R-eYFP were seeded onto glass bottom dishes

"dx.doi.org/10.1021/bi301107p" Biochemistry 2012, 51, 9513–9523
(MatTek Corp.). Forty-eight hours post-transfection, cells were washed and fixed with 4% paraformaldehyde for 1 h and permeabilized with 0.2% NP-40. Cells were incubated with rabbit polyclonal anti-Cav1 antibody (N20) (Santa Cruz Biotechnology) and then incubated with AlexaFluor secondary antibodies. Fixed cells were imaged with an Olympus Fluoview laser scanning microscope equipped with a 488 nm argon ion laser for excitation of eGFP, a 534 nm HeNe laser for Alexa 594, or a 633 nm HeNe laser for Alexa 647. No significant bleedthrough was observed from the eGFP or eYFP channel to the Alexa 647 channel. Colocalization analysis was performed using the MacBiophotonics version of ImageJ.

FRET Imaging. Sensitized emission FRET was performed with an Olympus Fluoview1000 instrument on HEK293 cells co-expressing eCFP- or eYFP-tagged proteins. eCFP and eYFP were excited using 458 and 515 nm argon ion laser lines, respectively, and 480−495 and 535−565 nm bandpass filters to collect emission images, respectively. The FRET efficiency was calculated by the method used by Chen and co-workers. Using this algorithm, FRET images are corrected for spectral bleedthrough by analyzing images of control cells expressing donor proteins alone or acceptor proteins alone with the same intensity distributions as the sample. Using controls with the same intensity distributions as the samples, we found that FRET efficiency values did not change significantly over a 10-fold range of acceptor:donor intensity ratios (e.g., Figure 5b).

Background FRET values were obtained by imaging cells co-expressing eCFP and eYFP. Positive control values were obtained using a dodecapeptide labeled with eCFP and eYFP on both ends (i.e., eCFP-X12-eYFP).

RESULTS

Distribution of Caveolae Domains in Cells. Before characterizing the effect of caveolae on the properties of B2R and μOR, we determined the cellular distribution of Cav1 in FRTcav+ cells by immunofluorescence (Figure 1a). FRT cells are polarized epithelial cells that exhibit basolateral and apical membranes. We find that Cav1 is mainly localized to the basolateral membrane and is sporadically distributed on the apical membrane. This is in agreement with the work of Mora and others, who found that more than ∼99% of Cav1 in transfected FRT cells preferentially goes to the basolateral membrane. Additionally, Cav1 is localized in regions of cell−cell contact. The observation that Cav1 is concentrated in cell contact regions correlates well with the observation that they may organize proteins involved in intercellular signaling, such as connexins.

We wanted to determine whether the presence of caveolae impacts the plasma membrane distribution of B2R and μOR. We looked at the z distribution of B2R-GFP and μOR-eGFP in FRTcav+ cells to see whether they would have a basolateral distribution similar to that of Cav1. We found that μOR has a uniform plasma membrane distribution on both the basolateral and apical membranes (Figure 1b). Alternately, B2R largely

(a) Top view

(b) Top view

Figure 1. (a) Immunofluorescence image of FRTcav+ cells showing the distribution of Cav1 as viewed from the top of the cells. The right panel is a side view of cells showing that Cav1 is mainly distributed on the basolateral region of the plasma membrane. (b) Distribution of μOR and B2R in FRT cells. μOR-eGFP in FRTcav+ cells shows a uniform distribution on the apical and basolateral membranes, while the majority of B2R-GFP localizes to the basolateral region of FRTcav+ cells, which is similar to the Cav1 distribution. This preferential localization of B2R to the basolateral membrane is not seen when it is expressed in FRTwt cells.
resides on the basolateral membrane, paralleling the distribution of Cav1 in contrast to μOR. To verify whether the distribution of B2R is caused by the presence of Cav1, we checked the z distribution of B2R in FRTwt cells, which do not have caveolae. In FRTwt cells, B2R did not exhibit a preferential localization on the basolateral membrane. These observations suggest that Cav1 is responsible for its basolateral localization.

Caveolae Affect Signals from B2R but Not from μOR. We determined whether the presence of caveolae alters the ability of μOR and B2R to generate second messengers. Stimulation of μOR by morphine activates Goi, which inhibits adenylyl cyclase, resulting in a decrease in the level of cellular cAMP. We assessed the decrease in cAMP levels in FRTwt and FRTcav+ cells transfected with μOR using a standard radiometric method (see Materials and Methods). We first verified that the receptor is expressed at similar levels in both cell types by visualizing the fluorescently tagged receptors in live cells. The results of these studies (Figure 2a) demonstrate that caveolae do not affect the cAMP response generated through μOR and Goi. For these cell types, stimulation of μOR and Goi did not increase the level of intracellular Ca2+ even at saturating morphine concentrations (0.1−50 μM).

We have previously found that the affinity between Cav1 and Goi is strengthened when Goi is activated through muscarinic receptors, resulting in a prolonged Ca2+ signal. Here, we tested whether a similar increase in the level of calcium is seen for B2R-mediated Goi activation. To this end, we measured the change in Ca2+ levels with bradykinin stimulation in FRTwt and FRTcav+ cells expressing B2R. In these studies, we compared intracellular Ca2+ release in wild-type cells and cells where expression of Cav1 was downregulated by ~50% [as estimated by Western blotting (see Materials and Methods)] through treatment with siRNA(Cav1) in wild-type cells, we find that at least one-third of the cells show a prolonged Ca2+ signal (i.e., >200 s) upon bradykinin stimulation that is similar to the behavior

![Figure 2](dx.doi.org/10.1021/bi301107p.png)
observed for carbachol stimulation of FRTcav+ cell suspensions. In the case of the Cav1 knockdown cells, none of the ~50 siRNA(Cav1) cells showed this prolonged Ca\(^{2+}\) recovery. In Figure 3, we show data extracted for several cells, although many more were viewed.

**Colocalization of B2R and \(\mu\)OR with Cav1.** The preferential basolateral localization of B2R (Figure 1b) and strengthened Ca\(^{2+}\) signals generated with B2R-G\(\alpha\)q activation (Figure 2b,c) in FRTcav+ cells suggest that B2R, but not \(\mu\)OR, interacts with caveolae domains. As a first step in determining whether this is the case, we measured the amount of colocalization between the receptors and Cav1, using the anti-Cav1 antibody. The results, summarized in Figure 4, show a significant colocalization between B2R-eYFP and Cav1 as seen (0.76 ± 0.01; \(n = 7\)) on the lateral membrane compared to a positive control consisting of Cav1-eGFP labeled with anti-Cav1 labeled with Alexa 647 in FRTwt cells (0.93 ± 0.01; \(n = 9\)) and a negative control consisting of Cav1-eGFP stained with secondary antibody (Alexa 647) alone (0.17 ± 0.02; \(n = 7\)). In contrast, a smaller amount of colocalization is seen between \(\mu\)OR-eGFP and Cav1 (0.51 ± 0.01; \(n = 9\)).

**B2R and \(\mu\)OR Interact Differently with Cav1 As Determined by Förster Resonance Energy Transfer.** Concern with colocalization measurements are the low spatial resolution and the dependence on the strength and specificity of the antibodies, as well as the exposure of the epitope that may be a problem with integral membrane proteins. To gain more sensitive localization information, we used FRET. Cav1 was tagged with an enhanced cyan fluorescent protein (eCFP) on its N-terminus, and B2R and \(\mu\)OR were tagged with an enhanced yellow fluorescent protein (eYFP) tag on their C-termini. HEK293 cells were chosen for their high transfection efficiency and the exclusive plasma membrane distribution of the receptors. Moreover, the usage of nonpolarized HEK293 cells removes artifacts that could arise from using FRT cells whose polarity might influence FRET results. Cells expressing eCFP-Cav1 and B2R-eYFP at similar levels were selected. The increase in eYFP emission in the presence of eCFP was then measured (see Materials and Methods). For the eCFP/eYFP pair, the distance at which 50% donor fluorescence is lost to transfer is 30 Å, and on the basis of the estimated size of the proteins, the presence of FRET should indicate physical association. FRET values for each sample were compared to a positive control consisting of eCFP-X\(_{12}\)-eYFP and a negative control consisting of free eCFP and eYFP expressed in the same cells (see refs 14 and 30). Additionally, we verified that a high level of FRET occurs between Cav1-eGFP and mcherry-Cav1, showing that the tagged Cav1 proteins can still oligomerize and form caveolae domains (data not shown). FRET results are summarized in Figure 5. Despite previous data suggesting that \(\mu\)OR localizes in caveolae domains, we could not detect significant FRET between Cav1 and \(\mu\)OR. In contrast, B2R and Cav1 display a weak but significant and

Figure 3. Single-cell measurements of Ca\(^{2+}\), as determined by Calcium Green (see Materials and Methods) for wild-type A10 cells and cells treated with siRNA(Cav1). Two wild-type traces are shown with empty symbols: (●) average of eight traces for the cell population (~70%) that displayed a short recovery and (□) a sample trace of cells in the 30% population that showed a prolonged recovery (~30%). (●) Average of seven traces for cells that have been treated with siRNA(Cav1). The SEM, which is not shown for the sake of clarity, ranged between 0.6 and 2.5% from the beginning to the recovery period for both types of circles and between 2.4 and 5.7% for the recovery. The error for the prolonged Ca\(^{2+}\) signal was large in the recovery period for both types of circles and between 2.4 and 5.7% for the error for the prolonged Ca\(^{2+}\) signal was large in the recovery period for both types of circles and between 2.4 and 5.7% for the recovery.
reproducible FRET, suggesting that a population of receptor localizes to these domains.

We find the value of $G_{\alpha q} - \text{Cav1}$ FRET is 2-fold higher than the value of $B_2R - \text{Cav1}$ FRET (Figure 5). Although other interpretations are possible, these results might suggest that $G_{\alpha q}$ has a higher degree of caveolae association than $B_2R$. We note that the higher level of FRET between $G_{\alpha q}$ and Cav1 than between $B_2R$ and Cav1 is unexpected because we have found a relatively high level of normalized FRET for $B_2R$-eYFP and $G_{\alpha q}$-eCFP (i.e., 24.7 ± 1.8 for FRTwt and 29.1 ± 3.3 for FRTcav+). Moreover, we have previously found that $B_2R$ forms a complex with $G_{\alpha q}G_{\beta \gamma}$ in the basal state of HEK293 cells. Nevertheless, the presence of FRET suggests close localization among $B_2R$, $G_{\alpha q}$, and Cav1.

**Role of $G_{\alpha q} - \text{Cav1}$ Interactions in $B_2R - \text{Cav1}$ Interactions.** Our FRET studies suggest that $G_{\alpha q} - \text{Cav1}$ interactions are stronger than $B_2R - \text{Cav1}$ interactions, and it is possible that $G_{\alpha q}$ is responsible for promoting $B_2R - \text{Cav1}$ interactions. If this is the case, then disrupting $G_{\alpha q} - \text{Cav1}$ interactions would eliminate $B_2R - \text{Cav1}$ FRET. Thus, we measured the amount of FRET between $B_2R$-eYFP and eCFP-Cav1 in the absence and presence of a microinjected caveolin peptide (DGIWKASFTFTVKYWFYRC), which interferes with the association between purified $G_{\alpha q}$ and partially purified membrane fractions containing overexpressed Cav1. This peptide, but not a control peptide with the same length and charge, also disrupts $G_{\alpha q} - \text{Cav1}$ colocalization in cultured cells and cardiomyocytes, although there is a possibility that the peptide might disrupt other Cav1 interactions.

HEK293 cells expressing $B_2R$-eYFP and eCFP-Cav1 at similar levels were microinjected with 200 nM peptide, and changes in $B_2R - \text{Cav1}$ FRET were determined (e.g., Figure 6a). By comparing the amount of FRET from microinjected versus uninjected cells to that in cells injected with 200 nM control peptide, we found that cells injected with caveolin peptide had significantly lower FRET values (Figure 6b). It is worth noting that the FRET values between $B_2R$-eYFP and eCFP-Cav1 in microinjected cells were similar to those of negative controls, suggesting that the amount of caveolin peptide microinjected is enough to disrupt the entire population of the $B_2R$-eYFP associated with Cav1. This study suggests that the population of $B_2R$-eYFP that participates in the transfer of energy from eCFP-Cav1 is mediated by interactions between $G_{\alpha q}$ and Cav1.

We further tested this idea by transfecting HEK293 cells with eCFP-Cav1 and $B_2R$-eYFP and measuring the decrease in the level of FRET with decreased levels of $G_{\alpha q}$ using siRNA-
mediated downregulation. $G_{\alpha q}$ was downregulated by $\sim 39 \pm 11\%$, as estimated by Western blotting. We note that the injected cell presented was one that gave a FRET value in the upper range for the purposes of display. (b) Summary of the change in eCFP-Cav1–B$_2$R-eYFP FRET in cells that were not injected ($n = 15$), cells injected with the Cav1 peptide ($n = 9$), or a control peptide ($n = 8$). ANOVA calculations show significant differences ($p < 0.001$) between un.injected and Cav1 peptide samples and between Cav1 peptide and control peptide data. (c) Study similar to that shown in Figure 5b except that in this study, $G_{\alpha q}$ was downregulated using siRNA (see the text). (d) FRET between B$_2$R-eYFP and eCFP-Cav1 in HEK293 membrane fractions mixed with activated (30 nM) ($G_{\alpha q}^*$ or $G_{\alpha i}^*$) or inactivated $G_{\alpha q}$ or $G_{\alpha i}$ (30 nM) in the absence and presence of 200 nM Cav1 peptide (+pep) or 200 nM control peptide (+ctr). FRET efficiencies were calculated from the increase in eYFP emission upon eCFP excitation. Data are means ± SEM, where $n = 3$ independent experiments.

Figure 6. (a) Raw images showing the change in FRET between eCFP-Cav1 and B$_2$R-eYFP before and after injection with a 200 nM solution of a peptide that disrupts $G_{\alpha q}$–Cav1 association (Cav1 peptide). We note that the injected cell presented was one that gave a FRET value in the upper range for the purposes of display. (b) Summary of the change in eCFP-Cav1–B$_2$R-eYFP FRET in cells that were not injected ($n = 15$), cells injected with the Cav1 peptide ($n = 9$), or a control peptide ($n = 8$). ANOVA calculations show significant differences ($p < 0.001$) between uninjected and Cav1 peptide samples and between Cav1 peptide and control peptide data. (c) Study similar to that shown in Figure 5b except that in this study, $G_{\alpha q}$ was downregulated using siRNA (see the text). (d) FRET between B$_2$R-eYFP and eCFP-Cav1 in HEK293 membrane fractions mixed with activated (30 nM) ($G_{\alpha q}^*$ or $G_{\alpha i}^*$) or inactivated $G_{\alpha q}$ or $G_{\alpha i}$ (30 nM) in the absence and presence of 200 nM Cav1 peptide (+pep) or 200 nM control peptide (+ctr). FRET efficiencies were calculated from the increase in eYFP emission upon eCFP excitation. Data are means ± SEM, where $n = 3$ independent experiments.

in the absence or presence of a control peptide (see above) resulted in a substantial increase in the level of FRET indicative of B$_2$R–Cav1 association (Figure 6d). This increase was reduced in the presence of the caveolin-1 peptide or deactivated $G_{\alpha q}$(GDP). Addition of activated or deactivated $G_{\alpha q}$ had no measurable effect on the level of FRET. Keeping in mind that the affinity of $G_{\alpha q}$(GTPyS) for B$_2$R is still high under conditions where downregulation does not occur (see ref 15), as is the case here, and that the affinity between Cav1 and activated $G_{\alpha q}$ is very high, this result shows that $G_{\alpha q}$ promotes association between B$_2$R and Cav1 and that the affinity between
Cav1 and Gαq(GDP) is not sufficiently high to displace endogenous proteins from Cav1.

**DISCUSSION**

In this study, we have determined the influence of caveolae on the properties of two GPCRs. The impetus for this work grew out of observations that certain signaling proteins, such as Gαq, partition into caveolae domains and this partitioning alters the properties of Gαq-generated signals (e.g., ref 31). Because many GPCRs that are coupled to Gα, as well as Gαq, have been reported to reside in caveolae, we wanted to determine the influence of this domain on GPCR signaling. We used fluorescence measurements on intact living cells to avoid some of the problems in interpreting results using methods that involve cell disruption. It is arguable that the fluorescent labels used in live cell studies may influence our results. However, the subcellular localization of these proteins and functional studies argue against this possibility.

We first found that Cav1, and presumably caveolae, are not evenly distributed in FRT cells. It is important to note that the localization of caveolae may differ depending on a variety of factors, including the cell type, the confluence, the migration state, or its stage in the mitotic cycle. In FRT cav+ cells, we observe Cav1 mainly on the basolateral membrane and in areas of cell–cell contact, supporting the idea that they may play a role in sensing contact inhibition or cell communication by organizing proteins such as connexins. It is notable that in muscle tissue in which cells are arranged in arrays, such as cardiomyocytes, caveolae have a dense and fairly uniform membrane distribution along actin lines (e.g., refs 17 and 37). In fluid cells, transformed cells, or immortalized cells, caveolae are absent or their level is greatly diminished. We also observed that the basolateral distribution of B2R mirrors that of Cav1 in these cells while the distribution of μOR does not.

We studied the effect of caveolae on the functional and physical properties of two types of GPCRs, B2R and μOR, which have both been found to localize in caveolae domains. μOR and B2R are coupled to two different families of G-proteins, Gαi and Gαq, respectively. Cav1 expression does not appear to affect cAMP signals generated through μOR and Gαq. It is noteworthy that stimulation of the μOR–Gαq pathway may also increase the level of intracellular Ca2+, possibly through coactivation of a Gαq-coupled receptor or by the release of Gβγ subunits that can then activate PLC/β or PLC/δ. However, in our hands, FRTwt and FRTcav+ cells expressing μOR did not exhibit intracellular Ca2+ release. In contrast, Ca2+ signaling through the B2R pathways is clearly affected by the presence of caveolae as seen in both single-cell and cell suspension measurements similar to the behavior seen for muscarinic receptors. It is important to note that the effect of caveolae on Ca2+ release is seen immediately after stimulation and before detachment of B2R from Gαq and the subsequent sequestration because Gαq−B2R FRET is constant for the first 2 min after stimulation. This effect of caveolae on Ca2+ signals is interpreted to be due to stabilization of the activated state of Gαq by strong Cav1 binding and release of Gβγ from caveolae domains, which lengthens the time for recombination of the heterotrimer. These studies and our findings presented here suggest that both B2R and muscarinic receptors may reside in or close to caveolae.

We find both receptors colocalize with Cav1. It is notable that Head and co-workers found that μOR and Cav3 colocalize to a higher degree in adult cardiomyocytes, although direct comparison between their studies and ours is difficult because Cav3 shows a much higher level of expression and is uniformly distributed throughout cardiomyocytes as opposed to FRT cells. Additionally, the C-terminus of Cav3 is significantly different from Cav1, which may allow direct or indirect μOR binding. It is notable that the resolution of colocalization measurements is quite low compared to that of FRET, and we could not detect a significant amount of FRET between μOR and Cav1 but did find a small (∼20%) amount FRET between B2R and Cav1. Additionally, we observed a larger amount of FRET between Gαq and Cav1, implying that Gαq is localized within caveolae domains. We also observe an equally large amount of FRET between Gαq and B2R (Figure 3 and ref 15). Together with our functional results, these data show that Gαq can interact with Cav1 and change its signaling properties while being in the proximity of B2R. The lower level of FRET observed between B2R and Cav1 compared to that between Gαq and Cav1 might be correlated to a weaker interaction, although it could also be traced to orientations of eCFP and eYFP that make transfer less favorable.

Our data show that Cav1 stabilizes Gαq-mediated Ca2+ signals generated through bradykinin in B2R-transfected cells. This receptor population is large enough to undergo FRET with Cav1 on the nanosecond time scale and to influence Gαq signaling. The level of Gαq−Cav1 FRET is 2-fold higher than the level of B2R−Cav1 FRET, despite the high FRET values between B2R and Gαq. One explanation of this result is that GPCRs do not significantly penetrate into Cav1 domains and their association depends on the strength of their attached Gα family. Gαq which interacts strongly with Cav1, promotes caveolae localization of its coupled receptors, while Gαi-coupled receptors, such as μOR, have little interaction with these domains, although they might incorporate into non-caveolae cholesterol-rich domains. Our fluorescence and functional studies suggest that the interaction between B2R and Cav1 could be mediated through Gαq. We find a loss of B2R−Cav1 FRET when Gαq is downregulated or displaced from caveolae, and we find that Gαq but not Gαi increases the level of FRET between B2R and Cav1. These results also suggest that GPCRs that do not couple to Gαq such as μOR would not localize to caveolae with the overexpression of Gαq. The idea that G-proteins mediate receptor association with caveolae is also supported by observations that μOR and B2R can be preassembled with their G-protein subunits, and that Gαq but not other G-proteins, interacts with Cav1. Additionally, previous FRET studies suggest that Gαq can interact simultaneously with Gβγ, B2R, and Cav1.

Even though FRT cells have been used extensively to study caveolae, we tested the effects of caveolae on Ca2+ signals mediated through bradykinin in A10 cells that endogenously express B2R and Cav1. Single-cell measurements show two distinct Ca2+ responses that we interpret to be due to caveolae and non-caveolae localized Gαq. The basis for these two populations is uncertain. It is possible that only ∼30% of A10 cells have fully formed caveolae domains where Gαq can properly localize and impact the signaling. On the basis of the localization of caveolae on plasma membranes, we suggest that the caveolae-localized Gα population is in regions of cell–cell contact. This idea leads to the hypothesis that signaling in intercellular regions differs from that in other regions of the cell.

It is possible that instead of stabilizing the activated state of Gαq, Cav1 mediates a step downstream of Gαq that is coupled...
to B2R and to muscarinic receptors. We have previously found that PLC/β associates strongly in a manner similar to that of Gtq in FRTwt and FRTcav+ cells, and because the activity of PLC/β is low in the basal state, its activity mirrors the activation state of Gtq which has been observed to be prolonged in the presence of caveolae. It is also possible that specific partitioning of PIP2 in caveole contributes to the observed changes in Ca2+ release, although preferential localization of PIP2 in caveole domains is controversial (see ref 4).

Interestingly, PIP2 was shown to localize to the periphery of caveole, where we suggest that the Gtq receptors localize. Partitioning of PIP2 in the neck of caveole would be expected to impact the magnitude of calcium release, which we see in FRTcav+ cells when they are stimulated with bradykinin, but we find that caveole impact the duration of the signal rather than the extent (Ref 4, Figures 2b and 3).

Support for the idea that GPCRs coupled to Gtq interact more extensively with caveole than receptors coupled to other G-protein families comes from several reports. Many receptors that are reported to be localized and/or internalized via caveole are coupled to Gtq (i.e., B2R, GnRH, serotonin 5HT2, TRH, and muscarinic receptor M3). With the exception of somastostatin SST2, where we suggest that Gtq receptors localize. Partitioning of PIP2 in the neck of caveole would be expected to impact the magnitude of calcium release, which we see in FRTcav+ cells when they are stimulated with bradykinin, but we find that caveole impact the duration of the signal rather than the extent (Figures 2b and 3).

Localization of signaling proteins in caveole would be expected to impact their signaling properties if this sequestration prevented or promoted access to proteins in their pathway. The studies here suggest that caveole may impact Gtq signaling without a direct incorporation of GPCRs into the domain. This idea might explain many of the controversial reports pertaining to GPCR–caveole associations. Super-resolution studies will aim to improve our understanding of the organization of these domains.

### ABBREVIATIONS

- A10 cells, rat aortic smooth muscle cells; B2R, bradykinin type 2 receptor; Cav1, caveole-1; eGFP, eCFP, and eYFP, enhanced green, cyan, and yellow fluorescent proteins, respectively; FRET, Förster resonance energy transfer; FRT cells, Fischer rat thyroid cells; GPCR, G-protein-coupled receptor; μOR, μ-opioid receptor; PIP2, phosphoinositol 4,5-bisphosphate; PLCβ, inositol specific mammalian phospholipase Cβ.
