(Dated: November 21, 2021)

The magnetic insulator yttrium iron garnet (YIG) with a ferrimagnetic transition temperature of ∼560 K has been widely used in microwave and spintronic devices. Anomalous features in the spin Seeback effect (SSE) voltages have been observed in Pt/YIG and attributed to the magnon-phonon coupling. Here we use inelastic neutron scattering to map out low-energy spin waves and acoustic phonons of YIG at 100 K as a function of increasing magnetic field. By comparing the zero and 9.1 T data, we find that instead of splitting and opening up gaps at the spin wave and acoustic phonon dispersion intersecting points, magnon-phonon coupling in YIG enhances the hybridized scattering intensity. These results are different from expectations of conventional spin-lattice coupling, calling for new paradigms to understand the scattering process of magnon-phonon interactions and the resulting magnon-polarons.

Spin waves (magnons) and phonons are propagating disturbance of the ordered magnetic moment and lattice vibrations, respectively. They constitute two fundamental quasiparticles in a solid and can couple together to form a hybrid quasiparticle [1 2]. Since our current understandings of these quasiparticles are based on linearized models that ignore all the high-order terms than quadratic terms and neglect interactions among the quasiparticle themselves [3], magnons and phonons are believed to be stable and unlikely to interact and breakdown for most purposes [4]. Therefore, discovering and understanding how the otherwise stable magnons and phonons can couple and interact with each other to influence the electronic properties of solids are one of the central themes in modern condensed matter physics.

In general, spin-lattice (magnon-phonon) coupling can modify magnon in two different ways. First, the static lattice distortion induced by the magnetic order may affect the anisotropy of magnon exchange couplings, as seen in the spin waves of iron pnictides with large in-plane magnetic exchange anisotropy [5]. Second, the dynamic lattice vibrations interact with time-dependent spin waves may give rise to significant magnon-phonon coupling [6 7]. One possible consequence of such coupling is to create energy gaps in the magnon dispersion at the nominal intersections of the magnon and phonon modes [8 9], as seen in antiferromagnet (Y,Lu)MnO3 [10]. Alternatively, magnon-phonon coupling may give rise to spin-wave broadening at the magnon-phonon crossing points [11]. In both cases, we expect the integrated intensity of hybridized excitations at the intersecting points to be the sum of separate magnon and phonon scattering intensity without spin-lattice coupling [8]. Finally, if magnon and phonon lifetime-broadening is smaller than their interaction strength, the resulting mixed quasiparticles can form magnon polarons [0 7].

Here we use inelastic neutron scattering to study low-energy ferromagnetic magnons and acoustic phonons in the ferrimagnetic insulator yttrium iron garnet (YIG) with chemical formula Y3Fe5O12 [Figs. 1(a)-1(d)] [12-14]. At zero field and 100 K, we confirm the quadratic wave vector dependence of the magnon energy, \( E = D q^2 \), where \( D \) is the effective spin wave stiffness constant and \( q \) is momentum transfer (in Å−1 or 1010 m−1) away from a Bragg peak [Fig. 1(e)] [13-19]. We also confirm the linear dispersion of the TA phonon mode [Fig. 1(e)]. Upon application of a magnetic field \( H_0 \), a spin gap of the magnitude \( gH_0 \) (\( g \approx 2 \) is the Landé electron spin g-factor) opens and lifts up spin waves spectra away from the field-independent phonon dispersion [Figs. 1(f) and 1(g)] [13-14]. By comparing the zero and 9.1 T field wave vector dependence of the spin wave spectra, we find that instead of splitting and opening up gaps at the spin wave and acoustic phonon dispersion intersecting points, hybridized magnon polaron scattering at the intersecting points has larger intensity at zero field and magnons remain unchanged at other wave vectors as shown schematically in the bottom panels of Figs. 1(f) and 1(g). This is different from the expectations of conventional magnon-phonon interaction, where hybridized polaronic excitations at the crossing points should have the sum of separate magnon and phonon scattering intensity, and become broader in energy due to the repulsive magnon-phonon dispersion curves [8 11]. Our results thus reveal a new magnon-phonon coupling mechanism, calling for a new paradigm to understand the scattering process of...
magnon-phonon interactions and the resulting magnon polarons [31].

We chose to study magnon-phonon coupling in YIG because it is arguably the most important material used in microwave and recent spintronic devices [20]. In addition to having a ferrimagnetic ordering temperature of ~560 K suitable for room temperature applications, YIG can be grown with exceptional quality, and has the lowest Gilbert damping of any known materials and a narrow magnetic resonance linewidth allowing transmission of spin waves over macroscopic distances [21,23]. The spin Seebeck effect (SSE), which allows spin currents produced by thermal gradients in magnetic materials to be transmitted and converted to charge voltages in a heavy metal such as Pt, is one of the most technologically relevant thermoelectric phenomena to be used in ‘spin caloritronic’ devices [24–29]. In the case of a Pt film on the surface of a polished single-crystalline YIG slab (Pt/YIG) [Fig. 1(c)] [30], anomalous features in magnetic field dependence of the SSE voltages at low temperatures are attributed to the magnon-phonon interaction at the “touching” points between the magnon and transverse acoustic (TA) and longitudinal acoustic (LA) phonon as magnon dispersion curve is lifted by the applied field while phonon is not affected by the field [Fig. 1(d)]. While we find no anomaly at the magnon and TA/LA acoustic phonon touching points, our data reveal clear evidence for magnon-phonon interaction at zero field, consistent with the formation of magnon polarons.

Our neutron scattering experiment was carried out at NIST center for neutron research, Gaithersburg, Maryland [32]. The full body-centered-cubic unit cell of YIG with space group Ia3d comprises eight cubes that are related by glide planes to the basic cube as shown in Fig. 1(a), where the metallic atomic sites are labelled as ‘a’, ‘d’, and ‘e’ [33]. Using the cubic lattice parameter of \( a = b = c = 12.376 \text{ Å} \), we define momentum transfer \( \mathbf{Q} \) in three-dimensional (3D) reciprocal space in \( \text{Å}^{-1} \) as \( \mathbf{Q} = H \mathbf{a}^* + K \mathbf{b}^* + L \mathbf{c}^* \), where \( H, K, \) and \( L \) are Miller indices and \( \mathbf{a}^* = \hat{a}2\pi/a, \mathbf{b}^* = \hat{b}2\pi/a, \mathbf{c}^* = \hat{c}2\pi/a \) [Figs. 1(a) and 1(b)]. Consistent with Ref. [34], the magnetic field dependence of SSE voltage on our Pt film on YIG contains two anomalous features at 2.5 T and 9.1 T [Figs. 1(c)-1(e)] [32–36].

The sample for neutron scattering experiments was oriented with \( a \) and \( b(a) \)-axis of the crystal in the horizontal \([H, K, 0]\) scattering plane [Fig. 1(b)] and mounted inside a 10 T vertical field magnet. In this geometry, we measured magnon dispersion around (2, 2, 0) and phonon dispersion around (4, 0, 0). The momentum transfers \( \mathbf{Q} \) at these wave vectors are \( \mathbf{Q}_{\text{magnon}} = (2 + \Delta Q, 2 + \Delta Q, 0) \) and \( \mathbf{Q}_{\text{phonon}} = (4, \Delta Q, 0) \) for TA phonon [Fig. 1(b)]. For convenience, we calculate relative momentum transfer as \( q = 2\pi\sqrt{2}\Delta Q/a \) for magnon and \( q = 2\pi\Delta Q/a \) for phonon. We chose (2, 2, 0) for magnetic and (4, 0, 0) for phonon measurements because of their huge differences in nuclear structure factors [4.75 at (2, 2, 0) versus 50.5 at (4, 0, 0)], which is directly related to the acoustic phonon intensity. Although we expect to find mostly magnetic scattering at (2, 2, 0) and phonon scattering at (4, 0, 0), the finite Fe\(^{3+}\) magnetic form factor of \( |F(Q)| \) means that there are still magnetic contributions to the phonon scattering at (4, 0, 0) \([|F(2, 2, 0)|^2/|F(4, 0, 0)|^2 \approx 1.86]\). Magnetic neutron scattering directly measures the magnetic scattering function \( S(Q, E) \), which is proportional to the imaginary part of the dynamic susceptibil-
The expected temperature, magnetic field dependence of low-energy $\chi''(Q,E)$ for simple ferromagnet obtained from SpinW software package [38]. Here the magnetic field induced spin gap $gH_0$ has been subtracted in the 9.1 T $\chi''(q, E-gH_0)$ (red). The upper and bottom units are $\Delta Q$ and $q$, respectively. (c) Our estimated $\chi''(Q,E)$ with $Q = (2.092,2.092,0)$ at 5 K and 100 K after correcting measured $S(Q,E)$ for the background and Bose-population factor. (d,e) The estimated $\chi''(Q,E)$ at 0 T and 9.1 T, respectively, after correcting for background and Bose population factor. Scans at different wave vectors are lifted up by 0.3 sequentially. The black and red arrows marks the peak positions at 0 T and 9.1 T, respectively.

energy of YIG at different temperatures and magnetic fields. Figure 2(c) shows our estimated constant-$Q$ scans $\chi''(Q,E)$ as a function of increasing wave vector at 0 T (black) and 9.1 T (red). The 9.1 T data is shifted by 1.05 meV to accommodate the field induced energy shift. Light red dots represents the original data position of the 9.1 T data. The horizontal bars are estimated instrumental energy resolution based on magnon dispersion at 100 K.

To determine if temperature and magnetic field dependence of spin waves in YIG follow these expectations, we measured wave vector dependence of magnon

FIG. 2: (a) Schematic illustration of the expected magnon dispersions at 0 T and 9.1 T for a simple ferromagnet. (b) The expected temperature, magnetic field dependence of low-energy $\chi''(Q,E)$ for simple ferromagnet obtained from SpinW software package [38]. Here the magnetic field induced spin gap $gH_0$ has been subtracted in the 9.1 T $\chi''(q, E-gH_0)$ (red). The upper and bottom units are $\Delta Q$ and $q$, respectively. (c) Our estimated $\chi''(Q,E)$ with $Q = (2.092,2.092,0)$ at 5 K and 100 K after correcting measured $S(Q,E)$ for the background and Bose-population factor. (d,e) The estimated $\chi''(Q,E)$ at 0 T and 9.1 T, respectively, after correcting for background and Bose population factor. Scans at different wave vectors are lifted up by 0.3 sequentially. The black and red arrows marks the peak positions at 0 T and 9.1 T, respectively.

FIG. 3: (a,b,c,d) Comparison of the estimated $\chi''(Q,E)$ as a function of increasing wave vector at 0 T (black) and 9.1 T (red). The 9.1 T data is shifted by 1.05 meV to accommodate the field induced energy shift. Light red dots represents the original data position of the 9.1 T data. The horizontal bars are estimated instrumental energy resolution based on magnon dispersion at 100 K.
Upon application of a 9.1 T field at 100 K, we expect the magnon dispersion curve to be lifted by $gH_0 \approx 1$ meV. This would be consistent with the observation of a sharp gap below 1.05 meV in constant-$Q$ scan at $Q = (2.012, 2.012, 0)$ ($\Delta Q \approx 0.012$) [Fig. 2(e)]. Constant-$Q$ scan at $Q = (2.032, 2.032, 0)$ shows similar behavior. Figure 2(e) also shows constant-$Q$ scans at identical wave vectors as those in Fig. 2(d) at 0 T. Using data in Fig. 2(e), we plot the magnon dispersion at 9.1 T field in Fig. 1(g). Consistent with the expectation, we see a clear $gH_0$ upward shift in magnon energy but the spin wave stiffness $D$ remains unchanged.

To quantitatively determine the magnetic field effect on $\chi''(Q, E)$ of YIG, we compare $\chi''(Q, E)$ at 0 T with those at 9.1 T. Figure 3(a)-3(d) summarizes the energy dependence of $\chi''(Q, E)$ after down shifting the 9.1 T data by $gH_0 = 1.05$ meV. At $\Delta Q = 0.062$, the scan along the red arrow direction near the magnon-phonon crossing point as shown in Fig. 1(f), we see that $\chi''(Q, E)$ at 9.1 T field is lower in intensity compared with those at 0 T. On moving to $\Delta Q = 0.10$ with no magnon-phonon crossing, $\chi''(Q, E)$ at 0 T and 9.1 T are virtually identical as expected. At the second magnon-phonon crossing point with $\Delta Q \approx 0.13$ [see red arrow in Fig. 1(g)], the differences between $\chi''(Q, E)$ at 0 T and 9.1 T are even more obvious, with intensity at 0 T considerably larger than that at 9.1 T [Fig. 3(c)]. Finally, on moving to $\Delta Q = 0.152$ well above the magnon-phonon crossing point wave vectors [Fig. 1(e)], we again see no obvious difference in $\chi''(Q, E)$ between 0 T and 9.1 T.

Figure 3 shows that magnetic field dependence of $\chi''(Q, E)$ is highly wave vector selective, revealing clear magnetic field induced intensity reduction in $\chi''(Q, E)$ at wave vectors associated with magnon-phonon crossing points while having no effect at other wave vectors. To confirm the presence of TA phonon and determine its magnetic field effect, we carried out TA phonon measurements near $(4,0,0)$, which has a rather large nuclear structure factor compared with $(2,2,0)$. Figure 4(a) shows energy scans of at $Q = (4, 0.2, 0)$ and 100 K, which is along the green arrow direction and near the magnon-phonon crossing point in Fig. 1(f). At 0 T, we see a peak around $E \approx 1.7$ meV consistent with dispersions of magnon and TA phonon. With increasing field to 2.5 T and 9.1 T, the intensity of the peak decreases, but its position in energy remains unchanged [Fig. 4(b)]. Figure 4(c) shows magnetic field dependence of the integrated intensity, confirming the results in Fig. 4(b). Since the energy of the magnon should increase with increasing magnetic field, the field independent nature of the peak position in Fig. 4(b) suggests that the mode cannot be a simple addition of magnon and phonon, but most likely arises from hybridized magnon polarons [6, 7]. Figure 4(d) shows the full width at half maximum (FWHM) of the magnon width at 0 T and 9.1 T. Within the errors of our measurements, we see no energy width change in the measured wave vector region.

Our results provided compelling evidence for the presence of magnon-phonon coupling in YIG at the magnon-phonon crossing points at zero field. This is clearly different from the SSE measurements, where anomalies are only seen at the critical fields that obey “touch” condition at which the magnon energy and group velocity agree with that of the TA/LA phonons. When the applied field is less than the critical field, the magnon dispersion has two intersections with TA/LA phonon modes. When the applied field is larger than the critical field, the magnon dispersion is separated from the TA/LA phonon modes. In the theory of hybrid magnon-phonon excitations [6, 7], the SSE anomalies occur at magnetic fields and wave vectors at which the phonon excitations are tangents to the magnon dispersion, where the effects of the magnon-phonon coupling are maximized [40].
While our findings of a novel magnon-phonon coupling at zero field are consistent with the formation of magnon-polarons in YIG [6, 7], they are not direct proof that magnon-polaron formation alone causes anomalous features in the magnetic field and temperature dependence of the SSE. Other effects, such as spin diffusion length, acoustic quality of the YIG film, and magnon spin conductivity also play an important role in determining the SSE anomaly [11]. Regardless of the microscopic origin of the SSE anomaly, our discovery suggests the need to understand why magnon-phonon interaction and the resulting magnon polarons enhance the hybridized excitations at the magnon-phonon intersection points.
