ABSTRACT
Collaborative beamforming enables nodes in a wireless network to transmit a common message over long distances in an energy efficient fashion. However, the process of making available the same message to all collaborating nodes introduces delays. The authors recently proposed a MAC-PHY cross-layer scheme that enables collaborative beamforming with significantly reduced collaboration overhead. The method requires knowledge of node locations and internode channel coefficients. In this paper, the performance of that approach is studied analytically in terms of average beampattern and symbol error probability (SEP) under realistic conditions, i.e., when imperfect channel estimates are used and when there are phase errors in the contributions of the collaborating nodes at the receiver.

Index Terms— collaborative beamforming, cross-layer approach for wireless networks, imperfect conditions

I. INTRODUCTION
Distributed, or collaborative, beamforming has been of considerable recent interest as a preferred solution for long-distance transmission in wireless networks, due to its energy efficiency [2],[3]. In conventional distributed beamforming schemes, a set of distributed nodes (called collaborating nodes) act as a virtual antenna array and form a beam to cooperatively transmit a common signal arising from a source node. Using knowledge of network coordinates, each collaborating node adjusts its initial phase so that the resulting beampattern focuses in the direction of the desired destination. The requirement that all collaborating nodes have access to the same message signal means that source nodes must share their message signals with collaborating nodes before beamforming. To study network performance, one must take into account the overhead (information-sharing time) required for node collaboration. If a time-division multiple-access (TDMA) scheme were to be employed, the information-sharing time would increase proportionally to the number of source nodes.

This work was supported by the National Science Foundation under Grants ANI-03-38807, CNS-06-25637 and CNS-04-35052, and by the Office of Naval Research under Grant ONR-N00014-07-1-0500.

II. SYSTEM MODEL AND PROPOSED SCHEME
The authors recently proposed a MAC-PHY cross-layer technique in [1] and [4], based on the idea of collaborative beamforming of [3], to reduce the time required for information sharing and to allow simultaneous multiple beams. The main idea is as follows: for information-sharing, we consider a real physical model in which collaborating nodes receive linear mixtures of transmitted packets. Subsequently, each collaborating node transmits a weighted version of its received signal. The weights allow packets bound to the same destination to add coherently at the destination node. Each collaborating node computes its weight based on the estimated channel coefficients between sources and itself, and also based on estimates of node coordinates. In [1] and [4] the analysis was performed under the assumption that all required estimates are perfect. In this paper, we investigate performance under imperfect conditions, i.e., when there are channel estimation errors and phase errors.
transmitting. (2) Nodes transmit packets consisting of phase-shift keying (PSK) symbols each having the same power $\sigma_i^2$. Communication takes place over flat fading channels. The channel gain during slot $n$ between source $t_i$ and collaborating node $c_j$ is denoted by $a_{ij}(n)$. For intra-cluster communications small-scale fading plays the dominant role. Thus, for a fixed $n$, we model $a_{ij}(n)$ as circularly symmetric complex Gaussian random variables with zero means and variances $\sigma_i^2$ (i.e., this is a Rayleigh fading model). The gains of different paths are assumed to be independent and identically distributed (i.i.d.). The gain of a given path is constant during the slot duration. (4) For inter-cluster communications, large-scale fading plays the dominant role. We assume that the distances between collaborating nodes and destinations are much greater than the maximum distance between source and collaborating nodes. Thus, the complex baseband-equivalent channel gain between nodes $c_i$ and $q_m$ during beamforming equals $b_m e^{j \delta_i d_m}$ [6], where $\lambda$ is the signal wavelength and $b_m$ is the path loss between the center of the disk containing the collaborating nodes and the destination.

In slot $n$, all source nodes within the cluster $C$ simultaneously transmit their packets. The packet transmitted by node $t_j$ consists of $L$ symbols $s_j(n) \triangleq [s_j(n; 0), \ldots, s_j(n; L-1)]$. Due to the broadcast nature of the wireless channel, non-active nodes in cluster $C$ hear a collision, i.e., a linear combination of the transmitted symbols. More specifically, node $c_i$ hears the signal

$$x_i(n) = \sum_{j=1}^{K} a_{ji}(n)s_j(n) + w_i(n) \quad (1)$$

where $w_i(n) = [w_i(n; 0), \ldots, w_i(n; L-1)]$ represents noise at the receiving node $c_i$. The noise is assumed to be zero-mean with covariance matrix $\sigma_w^2 I_L$, where $I_L$ denotes the $L \times L$ identity matrix.

Suppose that in slot $n + m$, $m = 1, \ldots, K$, the collaborating nodes need to beamform $s_m(n)$ to destination $q_m$. Each collaborating node $c_i$ transmits the signal

$$\hat{x}_i(n + m) = x_i(n)\mu_m a_{mi}(n)e^{-j \frac{2\pi}{\lambda}d_{im}} \quad (2)$$

where $e^{-j \frac{2\pi}{\lambda}d_{im}}$ is the initial phase of $c_i$. $\mu_m$ is a scalar used to adjust the transmit power; it is the same for all collaborating nodes, and is on the order of $1/N$.

Given the collaborating nodes at radial coordinates $r = [r_1, \ldots, r_N]$ and azimuthal coordinates $\psi = [\psi_1, \ldots, \psi_N]$, the received signal at an arbitrary location with polar coordinates $(d_{0m}, \phi)$, is

$$y(\phi; m|r, \psi) = \sum_{i=1}^{N} b_m \hat{x}_i(n + m)e^{j \frac{2\pi}{\lambda}d_{im}(\phi)} + v(n + m) \quad (3)$$

where $v(n + m)$ represents noise at the receiver during slot $n + m$. The covariance matrix of $v(n + m)$ equals $\sigma_v^2 I_L$.

The received signal at the destination $q_m$ during slot $n + m$ is

$$y(\phi_m; m|r, \psi) = \sum_{i=1}^{N} b_m \hat{x}_i(n + m) + v_m(n + m) \quad (4)$$

It was shown in [4] that, as $N \to \infty$ and omitting the noise, $y(\phi_m; m|r, \psi) \to N \mu_m b_m \sigma_m^2 s_m(n)$. Thus, the destination node $q_m$ receives a scaled version of $s_m(n)$. The beamforming step is completed in $K$ slots, reinforcing one source signal at a time. Compared with the scheme in [3], the information sharing time is reduced from $K$ to 1. Multiple beams can be formed in one slot when source packets have distinct destinations. In the rest of the paper, for simplicity we will consider only the case in which a single beam is formed during slot $n + m$, focusing on destination $q_m$.

### III. AVERAGE BEAMPATTERN UNDER IMPERFECT CONDITIONS

The beampattern represents the distribution of received power along all azimuthal angles. We showed in [4] that, under perfect conditions the average beampattern is of a form similar to [3], with increased sidelobe level. In this section, we discuss effects of imperfect channels and phase on average beampattern, respectively.

#### III-A. Imperfect Channels

We model $\hat{a}_{mi} = a_{mi} + \delta a_{mi}$ as the imperfect estimate of $a_{mi}$, where $\delta a_{mi}$ is the estimation error. The estimation errors are i.i.d. Gaussian random variables, $\delta a_{mi} \sim \mathcal{CN}(0, \sigma^2_a)$. The average beampattern with imperfect channels can be expressed as

$$\hat{P}_{av}(\phi) = E[|y(\phi; m|r, \psi)|^2] = P_{av}(\phi) + \delta P_{av}(\phi) \quad (5)$$

where $P_{av}(\phi)$ is the average beampattern related to perfect channels $a_{mi}$, and $\delta P_{av}(\phi)$ is the average beampattern...
related to the estimation error $\delta a_{mi}$. Following steps similar
to those leading to $P_{av}(\phi)$ in [4], one can obtain

$$\delta P_{av}(\phi) = \mu^2 b_m^2 E \left\{ \left| a_{mi} \right|^2 \sum_{i=1}^{N} \left| \delta a_{mi} \right|^2 \right\} + \sum_{j=1}^{K} \left( s_j \right)^2 \sum_{i=1}^{N} \left| \delta a_{mi} \right|^2 \left| a_{ji} \right|^2 + \sum_{i=1}^{N} \left| \delta a_{mi} \right|^2 \left| w_i \right|^2 \right\}$$

$$= N^2 \mu^2 b_m^2 \sigma_a^2 \left( \frac{K \sigma_a^2}{N \sigma_a} + \frac{\sigma^2}{N \gamma_1 \sigma_a} \right) \propto \frac{\sigma^2}{\sigma_a}$$

(6)

where $\gamma_1 \triangleq \sigma_a^2 \sigma_a^2 / \sigma_w^2$ represents the average SNR at the
collaborating nodes. Note that $\delta P_{av}(\phi)$ is actually a constant
independent of $\phi$. In other words, the effect of imperfect channels
on average beampattern is an increased sidelobe level.

III-B. Imperfect Phase

Under imperfect phase, each collaborating node $c_i$ will transmit
the signal $\tilde{x}_i(n + m) e^{i \tau_i}$, where the $\tau_i$ represents
the phase error, which is assumed i.i.d. with respect to $i$. We
use the same model as in [3] for the phase errors. Regarding
how to obtain the initial phase, two cases (closed-loop and open-loop) are considered (see [3] for details):

(1) For the closed-loop case, imperfect phase corresponds
to the phase offset due to the phase ambiguity caused by
carrier phase jitter or offset between the transmitter
and receiver nodes. We assume that the phase error $\tau$ follows a
Tikhonov distribution, which is a typical phase jitter model
for phase-locked loop (PLL) circuits.

(2) For the open-loop case, imperfect phase results from estimation
errors in the location parameters $r_i$ and $\psi_i$. We
assume the corresponding radius error $\delta r_i$ is uniformly distributed over $[-r_{max}, r_{max}]$, and the angle error $\delta \psi_i$ is uniformly distributed over $[-\psi_{max}, \psi_{max}]$. The radius and angle errors are further assumed to be mutually independent random variables, independent of $r_i$ and $\psi_i$.

Based on the above phase error models, we can show that
the expressions of the average beampattern are similar to the
results in Section VI of [3] with the only difference being a
scaling factor. Thus, as in [3], the basic effect of these
phase errors is in reducing the power in the main lobe. The
derivation is similar to that in [3] and is omitted here due to
space limitations.

IV. SEP UNDER IMPERFECT CONDITIONS

Under perfect conditions, the received signal (one sample)
at the destination is given by

$$y(\phi_m; m) = \mu b_m \sum_{i=1}^{N} \left| a_{mi} \right|^2 s_m + \mu b_m \sum_{i=1}^{N} a_{mi}^* \tilde{n}_i + v$$

(7)

where $\tilde{n}_i \triangleq \sum_{j=1}^{K} a_{ji} s_j + w_i$. We showed in [1] that $\tilde{n}_i \sim \mathcal{CN}(0, \sigma_n^2)$ where $\sigma_n^2 = (K - 1) \sigma_a^2 \sigma_a^2 + \sigma_w^2$.

Given $a_{mi}$, the instantaneous signal-to-interference-plus-noise ratio (SINR), $\gamma$, equals

$$\gamma = \frac{\mu^2 b_m^2 \sigma_a^2 \xi^2}{\mu^2 b_m^2 \sigma_a^2 \sigma_a^2 + \sigma_w^2}$$

where $\xi \triangleq \sum_{i=1}^{N} \left| a_{mi} \right|^2$ follows an Erlang distribution ($\xi \sim \text{Erlang}(N, \sigma_a^2)$).

Given $K$, the SEP for M-PSK symbols under perfect
conditions is [1], [5]

$$P_s(K) = \frac{1}{\pi} \int_{0}^{(M-1)\pi}\int_{0}^{\infty} \exp\left(-\frac{\sin^2(\pi/2\sigma_a^2)}{\sin^2(\varphi)}\right)$$

$$\times \frac{\xi^{N-1}e^{-\frac{\xi^2}{2\sigma_a^2}}}{\sigma_a^{2N}(N-1)!}d\xi d\varphi.$$

(9)

VA. Imperfect Channels

Taking channel errors into account, the received signal at
the destination is given by

$$y(\phi_m; m) = \mu b_m \sum_{i=1}^{N} \left| a_{mi} \right|^2 s_m + \mu b_m \sum_{i=1}^{N} a_{mi}^* \tilde{n}_i s_m + v$$

(10)

where $\tilde{n}_i \triangleq \sum_{j=1}^{K} a_{ji} s_j + w_i$. We showed in [1] that $\tilde{n}_i \sim \mathcal{CN}(0, \sigma_n^2)$ where $\sigma_n^2 = (K - 1) \sigma_a^2 \sigma_a^2 + \sigma_w^2$.

Given $a_{mi}$, the instantaneous signal-to-interference-plus-noise ratio (SINR), $\gamma$, equals

$$\gamma = \frac{\mu^2 b_m^2 \sigma_a^2 \xi^2}{\mu^2 b_m^2 \sigma_a^2 \sigma_a^2 + \sigma_w^2}$$

where $\xi \triangleq \sum_{i=1}^{N} \left| a_{mi} \right|^2$ follows an Erlang distribution ($\xi \sim \text{Erlang}(N, \sigma_a^2)$).

Given $K$, the SEP for M-PSK symbols under perfect
conditions is [1], [5]

$$P_s(K) = \frac{1}{\pi} \int_{0}^{(M-1)\pi}\int_{0}^{\infty} \exp\left(-\frac{\sin^2(\pi/2\sigma_a^2)}{\sin^2(\varphi)}\right)$$

$$\times \frac{\xi^{N-1}e^{-\frac{\xi^2}{2\sigma_a^2}}}{\sigma_a^{2N}(N-1)!}d\xi d\varphi.$$

(9)

IV-A. Imperfect Channels

Taking channel errors into account, the received signal at
the destination is given by

$$y(\phi_m; m) = \mu b_m \sum_{i=1}^{N} \left| a_{mi} \right|^2 s_m + \mu b_m \sum_{i=1}^{N} a_{mi}^* \tilde{n}_i s_m + v$$

(10)

where $\tilde{n}_i \triangleq \sum_{j=1}^{K} a_{ji} s_j + w_i$. We showed in [1] that $\tilde{n}_i \sim \mathcal{CN}(0, \sigma_n^2)$ where $\sigma_n^2 = (K - 1) \sigma_a^2 \sigma_a^2 + \sigma_w^2$.

Given $a_{mi}$, the instantaneous signal-to-interference-plus-noise ratio (SINR), $\gamma$, equals

$$\gamma = \frac{\mu^2 b_m^2 \sigma_a^2 \xi^2}{\mu^2 b_m^2 \sigma_a^2 \sigma_a^2 + \sigma_w^2}$$

where $\xi \triangleq \sum_{i=1}^{N} \left| a_{mi} \right|^2$ follows an Erlang distribution ($\xi \sim \text{Erlang}(N, \sigma_a^2)$).

Given $K$, the SEP for M-PSK symbols under perfect
conditions is [1], [5]

$$P_s(K) = \frac{1}{\pi} \int_{0}^{(M-1)\pi}\int_{0}^{\infty} \exp\left(-\frac{\sin^2(\pi/2\sigma_a^2)}{\sin^2(\varphi)}\right)$$

$$\times \frac{\xi^{N-1}e^{-\frac{\xi^2}{2\sigma_a^2}}}{\sigma_a^{2N}(N-1)!}d\xi d\varphi.$$

(9)

IV-A. Imperfect Channels

Taking channel errors into account, the received signal at
the destination is given by

$$y(\phi_m; m) = \mu b_m \sum_{i=1}^{N} \left| a_{mi} \right|^2 s_m + \mu b_m \sum_{i=1}^{N} a_{mi}^* \tilde{n}_i s_m + v$$

(10)

where $\tilde{n}_i \triangleq \sum_{j=1}^{K} a_{ji} s_j + w_i$. We showed in [1] that $\tilde{n}_i \sim \mathcal{CN}(0, \sigma_n^2)$ where $\sigma_n^2 = (K - 1) \sigma_a^2 \sigma_a^2 + \sigma_w^2$.

Given $a_{mi}$, the instantaneous signal-to-interference-plus-noise ratio (SINR), $\gamma$, equals

$$\gamma = \frac{\mu^2 b_m^2 \sigma_a^2 \xi^2}{\mu^2 b_m^2 \sigma_a^2 \sigma_a^2 + \sigma_w^2}$$

where $\xi \triangleq \sum_{i=1}^{N} \left| a_{mi} \right|^2$ follows an Erlang distribution ($\xi \sim \text{Erlang}(N, \sigma_a^2)$).

Given $K$, the SEP for M-PSK symbols under perfect
conditions is [1], [5]

$$P_s(K) = \frac{1}{\pi} \int_{0}^{(M-1)\pi}\int_{0}^{\infty} \exp\left(-\frac{\sin^2(\pi/2\sigma_a^2)}{\sin^2(\varphi)}\right)$$

$$\times \frac{\xi^{N-1}e^{-\frac{\xi^2}{2\sigma_a^2}}}{\sigma_a^{2N}(N-1)!}d\xi d\varphi.$$

(9)
IV-B. Imperfect Phase

Imperfect phase has two effects on the receiver: signal power reduction and phase distortion [2]. Assuming that the phase distortion is compensated for by the coherent receiver (e.g., by pilots), here we focus on signal power reduction only.

We define the power reduction coefficient $A_{\tau} = P_{\text{err}} / P_{\text{ideal}} \leq 1$, where $P_{\text{err}}$ is the average received signal power with phase error and $P_{\text{ideal}}$ is the average signal power under perfect phase.

Taking phase errors into account, the received signal at the destination is given by

$$y(\phi_m; m) = \mu_m b_m \sum_{i=1}^{N} |a_{mi}|^2 e^{j\tau_i} s_m + \mu_m b_m \sum_{i=1}^{N} a_{mi}^* \eta_i e^{j\tau_i} + v,$$  \hspace{1cm} (14)

where $\tau_i$ is the phase error of collaborating node $c_i$.

Note that the statistics of $\eta_i e^{j\tau_i}$ are identical to those of $\eta_i$; so phase errors do not change the statistical behavior of the interference term.

Assuming we use a coherent receiver, the instantaneous SINR, $\gamma_{ph}$, equals

$$\gamma_{ph} = \frac{\mu_m b_m^2 \sigma_s^2}{\mu_m b_m^2 \sigma_e^2 + \sigma_v^2} \left| \sum_{i=1}^{N} a_{mi} e^{j\tau_i} \right|^2.$$ \hspace{1cm} (15)

Since $|a_{mi}|^2$ and $e^{j\tau_i}$ are coupled, the exact SEP includes integration with respect to $a_{mi}$ and $\tau_i$ ($i = 1, \ldots, N$), which is computationally complex. To facilitate analysis we make the following approximation for $\gamma_{ph}$:

$$\gamma_{ph} \approx A_{\tau} \cdot \frac{\mu_m b_m^2 \sigma_s^2}{\mu_m b_m^2 \sigma_e^2 + \sigma_v^2} \left| \sum_{i=1}^{N} a_{mi}^2 \right| = A_{\tau} \cdot \gamma.$$ \hspace{1cm} (16)

In other words, $\gamma_{ph}$ is approximated by the instantaneous SINR under perfect conditions scaled down by a coefficient $A_{\tau}$.

It can be shown that

$$A_{\tau} = \frac{P_{\text{err}}}{P_{\text{ideal}}} = \frac{2 + (N - 1) \left| E \{ e^{j\tau_n} \} \right|^2}{N + 1},$$ \hspace{1cm} (17)

where $|E \{ e^{j\tau_n} \}|^2$ depends on the specific phase error model used. Based on the phase error models in section III-B, $|E \{ e^{j\tau_n} \}|^2$ has been derived in [3].

**Simulation:** In Fig.3(a), we show the SEP as a function of loop SNR $\rho_{\tau}$ (closed-loop case). The variance of the phase error is $1/\rho_{\tau}$. For the analytical SEP, we directly use the results in [3] to calculate $|E \{ e^{j\tau_n} \}|^2$ and obtain $A_{\tau}$ in (17).

As observed, $\rho_{\tau} > 10$ dB may be necessary to achieve a satisfactory SEP. Fig.3(b) shows the SEP vs. $r_{\text{max}} / R$ and $\psi_{\text{max}} / (2\pi)$ (open-loop case), where both radius and angle errors are considered. One can see that the phase error in the open-loop case can severely degrade the SEP performance.

Thus, it is important to investigate techniques that enable accurate location estimation. In both figures, the analytical result based on (16) match well the experimental results for a wide range of phase errors.

V. CONCLUSIONS

We have considered the cross-layer collaborative beamforming approach of [1] and [4], and we have analyzed its performance under imperfect conditions. For the average beampattern, the principal effect of imperfect channel information is increased sidelobe level, and the principal effect of imperfect phase information is reduced mainlobe power.

We have provided approximate analytical expressions for the SEP under imperfect conditions, which show the effects of imperfect channel and phase on that quantity.
