Summary

The pharmaceutical industry faces a growing demand and recurrent shortages in many anticancer plant drugs given their extensive use in human chemotherapy. Efficient alternative strategies of supply of these natural products such as bioproduction by microorganisms are needed to ensure stable and massive manufacturing. Here, we developed and optimized yeast cell factories efficiently converting tabersonine to vindoline, a precursor of the major anticancer alkaloids vinblastine and vincristine. First, fine-tuning of heterologous gene copies restrained side metabolites synthesis towards vindoline production. Tabersonine to vindoline bioconversion was further enhanced through a rational medium optimization (pH, composition) and a sequential feeding strategy. Finally, a vindoline titre of 266 mg l\(^{-1}\) (88% yield) was reached in an optimized fed-batch bioreactor. This precursor-directed synthesis of vindoline thus paves the way towards future industrial bioproduction through the valorization of abundant tabersonine resources.

Introduction

Vinblastine and vincristine are two major anticancer monoterpene indole alkaloids (MIAs) accumulated in the leaves of Catharanthus roseus and extensively used in human chemotherapies. Due to a constantly growing demand, both vinblastine and vincristine are suffering from recurrent shortages caused by socio-economic (e.g. demand pressure) and/or geopolitical and climatic constraints (Rabin, 2019). Additionally, the intensive culture of C. roseus conducted for the supply of these two drugs has a dramatic negative impact on the environment (e.g. water resource, pollution...) driving to the necessity of alternative methods for more sustainable production according to the Sustainable Development Goals (SDGs) of the United Nations (https://www.un.org/sustainabledevelopment/sustainable-development-goals). In such a perspective, the bioproduction of MIAs in heterologous hosts constitutes an attractive option to ensure a stable supply to the pharmaceutical industry (Courdavault et al., 2020). Among all generally regarded as safe (GRAS) microorganisms, Saccharomyces cerevisiae (baker yeast) displays many advantages such as a well-known sequenced genome, as well as numerous molecular tools for genetic manipulation and constitutes a highly valuable platform for industrial bioproduction of plant natural products (Guirimand et al., 2020). Since both vinblastine and vincristine derive from the condensation of catharanthine and vindoline, a stable supply of these two anticancer compounds could rely on the development of yeast cell factories by metabolic engineering of S. cerevisiae to produce vindoline and catharanthine as precursors. Conceptually, the vindoline synthesis can be performed either de novo (i.e. from glucose as original carbon source) or through precursor-directed synthesis by feeding engineered yeast with tabersonine, extractible at multigram scale from the...
highly abundant seeds of *Voacanga africana* (Kikura-Hanjiri *et al.*, 2009; Koroch *et al.*, 2009). In this case, seven enzymatic steps are required for the biotransformation of tabersonine (Fig. 1A; Qu *et al.*, 2015). Although the bioproduction of vindoline by yeast cell factories has been previously reported, the synthesis remains at a scarce level and thus requires optimization to reach industrial scale (Qu *et al.*, 2015).

In the present study, the tabersonine-to-vindoline biosynthetic pathway from *C. roseus* was stably integrated within hotspots of the genome of *S. cerevisiae*, using CRISPR-Cas9 molecular tools (Mikkelsen *et al.*, 2012). The fine-tuning of the copy numbers of the pathway genes and the optimization of the fermentation conditions allowed us to synthesize an unprecedented amount of vindoline, thus paving the way for a complementary production process of anticancer MIAs through metabolic engineering combined with the valorization of a renewable natural resource.

**Results and discussion**

*Engineering of a vindoline-producing yeast strain*

The bioconversion of tabersonine to vindoline requires seven enzymatic steps starting with T16H hydroxylating tabersonine (1) at carbon 16 to form 16-hydroxytabersonine (2), which is further methylated by 16OMT to 16-methoxytabersonine (3) (Qu *et al.*, 2015). Downstream conversion to 16-methoxytabersonine epoxide (4) is catalysed by T3O, which in turn is reduced to 16-methoxy-2,3-dihydro-3-hydroxytabersonine (5) by T3R. In the following steps, the T3R product is converted to desacetoxyvindoline (6) by NMT, then hydroxylated to deacetylvin-doline (7) by D4H and finally converted to vindoline (8) by DAT (Fig. 1A; Courdavault *et al.*, 2014). However, substrate promiscuity enables T3O using tabersonine directly to form tabersonine imine alcohol (9) (Kellner *et al.*, 2015). This marks the onset of a parallel branch pathway leading to the production of undesirable by-products including 2,3-dihydro-3-hydroxytabersonine (10), desacetoxyvindorosine (11), deacetylvin-dorosine (12) and vindorosine (13), whose *in planta* amounts depend on T16H expression level (Besseau *et al.*, 2013). Consequently, the heterologous production of vindoline may face suboptimal flux according to the initial decoration of tabersonine by T16H or T3O.

In order to create yeast cell factories producing vindoline from tabersonine, we selected the prototrophic *S. cerevisiae* strain CEN.PK113-7D, commonly used in metabolic engineering for industrial purposes. We initially implemented the five first genes of the tabersonine-to-vindoline biosynthetic pathway to produce desacetoxyvindoline through tabersonine transformation (strain T3110). T16H2, 16OMT, T3O, T3R, NMT coding sequences and ATR2 (required for T16H and T3O reduction) were integrated into three distinct hotspots of the *S. cerevisiae* genome, selected for high transcription activity (Mikkelsen *et al.*, 2012), under strong glycolytic promoters (Table S2). To assess the production of desacetoxyvindoline, the T3110 strain was fed with 125 μM of tabersonine and grown for 120 h. Culture medium was collected every 24 h, and extracellular metabolite content was analysed by liquid chromatography coupled with mass spectrometry (LC-MS) since the majority of alkaloids are accumulated in the extracellular medium (Qu *et al.*, 2015; Fig. S1A). Although tabersonine was not fully consumed after 24 h, the T3110 strain produced both desacetoxyvindoline and desacetoxyvindorosine in similar proportions (Fig. 1B). This confirms that the metabolic flux is simultaneously directed towards vindoline and vindorosine pathways as a result of T16H and T3O competition for tabersonine consumption. Therefore, in order to limit the vindorosine accumulation and improve the efficiency of tabersonine bioconversion, one additional copy of both T16H and 16OMT genes was introduced into the T3110 strain. The resulting daughter strain, named Q7, showed an 11-fold decrease of desacetoxyvindorosine accumulation, while desacetoxyvindoline drastically increased and the tabersonine was almost completely consumed after 24 h. Due to this improved metabolism and given that further increase in T16H/16OMT gene copy number did not impact desacetoxyvindoline production (Q112 strain), the Q7 strain was used as a background for the downstream integration of the final vindoline biosynthesis steps D4H and DAT. The resulting P12 strain, containing a single copy of D4H and DAT, produced 14.7 mg l⁻¹ of vindoline (Table S3). However, an important accumulation of desacetoxyvindoline was also observed, highlighting a D4H-dependent bottleneck. To circumvent this lack of activity, a total of three copies of both D4H and DAT genes were introduced into the Q7 strain to generate the Hep3 strain. As a consequence, the addition of two supplemental copies of D4H and DAT increased vindoline production up to 26.8 mg l⁻¹ after 120 h (i.e. two times higher than P12 strain) and halved the accumulation of desacetoxyvindoline. Interestingly, adding a fourth copy of both D4H and DAT genes did not improve vindoline titre (Hep122 strain), suggesting that other parameters such as culture conditions could be limiting rather than the number of gene copies. Moreover, after 72–96 h the bioconversion was reaching a plateau, which is probably due to the depletion of nutrients in the medium and an increasing competition with native metabolism for cofactors. Thus, Hep3 strain was selected for further optimization of vindoline production.

Optimization of culture conditions to enhance vindoline production

In order to evaluate the potential effect of culture medium and nutrient supply on the production of vindoline by the vindoline-producing strain Hep3, several sources of peptone nutrients (Table S3) were assayed. Compared with the bovine peptone (BovMP) routinely used, another peptone produced from bovine tissues (BovP), a peptone obtained from a mix of bovine and porcine tissues (BovPrCP), as well as trypptone and polypeptone (PolyP), showed drastic negative effects on the activity of NMT and D4H leading to the accumulation of intermediates 5 and 6, along with the poor production of vindoline (Fig. S1B). Consequently, BovMP was selected for further optimization of culture conditions. Above all, these results demonstrate that growth media composition has an acute effect on bioproduction underlining the importance of a careful choice of peptone sources.

Similarly, the pH of the culture medium was found to drastically impact the production of vindoline, pH 6.0 being determined as optimal (Fig. S1C). As the acidification of 2 points of the culture medium pH was observed after 120 h (Table S3), the importance of maintaining a constant level of optimal pH was investigated. In parallel, to prevent any starvation-related metabolic stress, the supply with fresh YP nutrients (yeast extract and peptone) every 24h after 48h of culture was assessed. The best vindoline production of 34.6 mg l⁻¹ was achieved by adding YP (condition YP₄₈h), which demonstrated an enhanced activity of D4H after 96h of culture and a 1.5-fold increase in vindoline titre compared with standard conditions (condition BovMP) (Fig. 2A, Table S3). Interestingly, the sole addition of YP was sufficient to maintain pH close to 6.0, driving to a slightly higher vindoline production compared with additional buffering of culture medium (condition pHP₄₈h). Hence, using BovMP peptone as the best source of nutrients and supplementing the culture with YP every 24 h from 48 h post feeding was defined as the optimal conditions for vindoline production.

Scaling up and engineering of bioreactor feeding to improve vindoline production

In order to scale up the production of vindoline, the Hep3 strain was next cultivated in bioreactors. In control conditions, both wild-type and Hep3 strains showed similar maximal growth rates (0.37 and 0.36 h⁻¹ respectively), viability (maintained up to 98%), as well as biomass and ethanol yields on glucose. This tends to show that overexpression of the vindoline pathway in the recombinant strain was well tolerated and did not constitute any utter metabolic burden for the cells. However, the addition of tabersonine into the culture medium increased the cellular respiration on oxygen, while the maximal growth rate showed a 20% decrease (Table 1). Such phenomenon, routinely observed with the addition of weak acid (Verduyn et al., 1992), reveals an uncoupling effect of tabersonine on energy and biomass productions that did not alter cell viability in all of the experiments (up to 98% in all the cultivations) (Fig. S2).

The F1 feeding experiment in the bioreactor was based on the best production strategy previously defined, relying on 24 h-pulsated supplementations of glucose followed by YPD addition. In these conditions, the conversion yield was found to be two times lower than in small-scale experiments (Table 1). However, the speed of production of vindoline was two times higher, with a maximal amount of vindoline produced within only 60 h, while the competing flux leading to the formation of vindorosine remained low (Fig. 2B; Fig. S2). In addition, except for the last stage of the starting pulse, a substantial decrease in vindoline cumulated mass was observed when glucose and ethanol were depleted, thus suggesting its consumption (Fig. S2). Therefore, in order to improve vindoline production, culture conditions were further optimized. For instance, glucose depletion between pulses was avoided by continuous feeding of growth substrates (F2 cultivation). Such feeding led to a 3 times faster conversion (22 h) than in the F1 reference culture, and consequently to higher productivity (Fig. 2B; Table 1).
Table 1). In addition, vindoline was also continuously synthesized and not degraded any longer, even 3 days after the synthesis ended (Fig. S2). Moreover, while many biosynthetic intermediates were accumulated in the F1 condition, they were only detected in minute amounts after 22 h of bioconversion in F2, as a result of an extended MIA biosynthetic enzyme activity (Fig. 2B). Above all, this suggests that an active central primary metabolism is critical to provide sufficient amounts of cofactors required by the heterologous pathway, such as acetyl-coA and NADPH.

In the next step, we investigated the intensification of the vindoline production by numbering-up the pulses of tabersonine (F3 cultivation). Interestingly, growth and production were maintained all over the culture, and a circa 50% increase in the conversion yield was observed compared with F2 culture (Fig. 2B; Table 1). This marked increase probably resulted from cell environment management, reducing the impact of tabersonine uncoupling effect that induces huge pH and pO₂ drops. Nevertheless, the tabersonine flux towards vindorosine highly increased at the expense of the vindoline pathway resulting in a 3:1 vindoline/vindorosine ratio (Table 1; Fig. 2B; Fig. S2). In addition, a higher accumulation of biosynthetic intermediates was also monitored during the whole experiment. To prevent the formation of undesired products and reduce heterologous pathway bottlenecks, we combined an uninterrupted active central metabolism (continuous glucose feeding under the Crabtree effect’s critical uptake rate, avoiding ethanol production) with a restrained consumption rate of tabersonine (Fig. S2). Accordingly, we limited the specific uptake rate of tabersonine under its maximal value (1.03 ± 0.04 mg g⁻¹ h⁻¹) through a continuous feeding in the F4 cultivation (Fig. S2; Fig. S3B). This strategy prevented tabersonine accumulation in the medium after 10 h and led to a 88% tabersonine bioconversion into vindoline, which was equivalently replicated (Fig. S3A). As a consequence, very low levels of vindorosine and vindoline biosynthetic intermediates were observed. (Table 1; Fig. 2B; Fig. S2; Fig. S3A). Thus, the control of central and heterologous metabolic fluxes by rational process design appeared as a relevant strategy to further improve vindoline production. In these conditions, vindoline reached a final titre of 266 mg L⁻¹ after 96 h of culture, and thus, 20-fold higher productivity than the original biosynthesis reported by Qu et al. (2015) with an episomal strain. To date, it constitutes the highest vindoline production ever reported, in terms of yield, titre and productivity.

Conclusions

Through a fine-tuned integration of heterologous biosynthetic genes combined with the optimization of culture conditions, we generated a yeast strain synthesizing high amounts of vindoline via the bioconversion of tabersonine (88% yield). Based on the quantity of tabersonine accumulated in the seeds of V. Africana and annual exportation of 1600 tons of seeds, the total production of 22.5 tons of vindoline can be expected using this newly developed yeast strain (Kikura-Hanajiri et al., 2009; Koroch et al., 2009). This advance thus opens new perspectives towards the development of a potential alternative supply of vindoline to avoid vinblastine and vincristine shortage in the future.
