Evolution of the longitudinal and azimuthal structure of the near-side jet peak in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 2.76$ TeV

ALICE Collaboration

Abstract

In two-particle angular correlation measurements, jets give rise to a near-side peak, formed by particles associated to a higher $p_T$ trigger particle. Measurements of these correlations as a function of pseudorapidity ($\Delta\eta$) and azimuthal ($\Delta\phi$) differences are used to extract the centrality and $p_T$ dependence of the shape of the near-side peak in the $p_T$ range $1 < p_T < 8$ GeV/$c$ in Pb–Pb and pp collisions at $\sqrt{s_{\text{NN}}} = 2.76$ TeV. A combined fit of the near-side peak and long-range correlations is applied to the data and the peak shape is quantified by the variance of the distributions. While the width of the peak in the $\Delta\phi$ direction is almost independent of centrality, a significant broadening in the $\Delta\eta$ direction is found from peripheral to central collisions. This feature is prominent for the low $p_T$ region and vanishes above 4 GeV/$c$. The widths measured in peripheral collisions are equal to those in pp in the $\Delta\phi$ direction and above 3 GeV/$c$ in the $\Delta\eta$ direction. Furthermore, for the 10% most central collisions and $1 < p_{T,\text{assoc}} < 2$ GeV/$c$, $1 < p_{T,\text{trig}} < 3$ GeV/$c$ a departure from a Gaussian shape is found: a depletion develops around the centre of the peak. The results are compared to AMPT model simulations as well as other theoretical calculations indicating that the broadening and the development of the depletion is connected to the strength of radial and longitudinal flow.

1 Introduction

In elementary interactions with large momentum transfer \( (Q^2 \gg \Lambda_{\text{QCD}}^2) \), partons with high transverse momentum \( (p_T) \) are produced. Carrying net colour charge, they cannot exist freely and, instead, evolve from high to low virtuality producing parton showers. These eventually hadronize into a spray of collimated hadrons called jets. High-\( p_T \) partons are produced at the early stages of heavy-ion collisions. They propagate and evolve through the dense and hot medium created in these collisions and are expected to lose energy due to induced gluon radiation and elastic scatterings, a process commonly referred to as jet quenching. The transfer of energy from the leading parton to the medium and/or into additional gluon radiation leads to effects that can be exploited to characterise the colour density and scattering power of the medium.

Experimental methods to study high-\( p_T \) parton production differ in their capability to reconstruct the original parton momentum and to characterize the angular and momentum distribution of jet fragments. Furthermore, their sensitivity to experimental bias, most particularly the bias associated with the large underlying-event background encountered in heavy-ion collisions, is different. Inclusive hadron spectra are unbiased observables, mainly sensitive to the hadronic fragments with the largest momentum fraction (leading particles). Partonic energy loss suppresses high-\( p_T \) particle yields relative to their production in more elementary pp and p–A collisions which was observed at RHIC and LHC energies. The largest suppression is observed in central Pb–Pb collisions at \( p_T \approx 7 \text{ GeV/}c \) [1, 2].

Jet reconstruction algorithms have the objective to recombine a maximum of jet fragments within a certain area in the pseudorapidity (\( \eta \)) - azimuth (\( \phi \)) plane in order to obtain the original parton energy and direction. In heavy-ion collisions, due to the large fluctuating energy from particles uncorrelated to the jets, the underlying event, jet reconstruction is limited to high transverse energy and small areas (cone-size) around the parton direction. An inclusive jet suppression commensurable to that of hadrons has been observed at the LHC [3–5] together with a large di-jet energy asymmetry [6, 7], suggesting that a large fraction of the lost energy is radiated outside the typical jet cone sizes of \( R = 0.3–0.5 \). Detailed studies of the energy balance in events with high-energy jets show that the lost energy reappears primarily at low to intermediate \( p_T \) (0.5–3 GeV/\( c \)) outside the jet cone [7]. Studies of the momentum and angular distributions of jet fragments show that the jet core is almost unmodified [8–10].

Di-hadron angular correlations represent a powerful complementary tool to study jet quenching and the redistribution of energy in an energy region where jets cannot be identified event-by-event over the fluctuating background and where quenching effects are expected to be large. Such studies involve measuring the distributions of the relative azimuthal angle \( \Delta \phi \) and pseudorapidity \( \Delta \eta \) between particle pairs. The pairs consist of a trigger particle in a certain transverse momentum \( p_{T,\text{trig}} \) interval and an associated particle in a \( p_{T,\text{assoc}} \) interval. In these correlations, jets manifest themselves as a peak centred around \( (\Delta \phi = 0, \Delta \eta = 0) \) (near-side peak) and a structure elongated in \( \Delta \eta \) at \( \Delta \phi = \pi \) (the away-side or recoil-region). At low \( p_T \), resonance decays as well as femtoscopic correlations also contribute to the near-side peak. The advantage of using di-hadron correlations is that an event-averaged subtraction of the background from particles uncorrelated to the jet can be performed. This advantage is shared with the analysis of hadron-jet correlations recently reported in Ref. [11, 12].

At RHIC, the near-side associated particle yield and peak shape have been studied for different systems and collision energies [13–15]. Small modifications of the yields with respect to a pp reference from PYTHIA are observed and there is remarkably little dependence on the collision system at the centre-of-mass energies of \( \sqrt{s_{\text{NN}}} = 62.4 \) and 200 GeV. An exception is the measurement in central Au–Au collisions at \( \sqrt{s_{\text{NN}}} = 200 \) GeV where the jet-like correlation is substantially broader and the momentum spectrum softer than in peripheral collisions and than those in collisions of other systems in this kinematic regime.

At the LHC, the measurement of the yield of particles associated to a high-\( p_T \) trigger particle (8–
15 GeV/c in central Pb–Pb collisions relative to the pp reference at $p_{T,\text{assoc}} > 3$ GeV/c shows a suppression on the away-side and a moderate enhancement on the near-side indicating that medium-induced modifications can also be expected on the near side [16]. Much stronger modifications are observed for lower trigger and associated particle $p_T$ ($3 < p_{T,\text{trig}} < 3.5$ GeV/c and $1 < p_{T,\text{assoc}} < 1.5$ GeV/c) [17, 18]. In the most central Pb–Pb collisions, the near-side yield is enhanced by a factor of 1.7.

The present paper expands these studies at the LHC to the characterisation of the angular distribution of the associated particles with respect to the trigger particle. The angular distribution is sensitive to the broadening of the jet due to the degradation of its energy and the distribution of radiated energy. Moreover, possible interactions of the parton shower with the collective longitudinal expansion [19, 21] or with turbulent colour fields [22] in the medium would result in near-side peak shapes that are broader in the $\Delta \eta$ than in the $\Delta \phi$ direction. Results from the study of the near-side peak shape of charged particles as a function of centrality and for different combinations of trigger and associated particle $p_T$ are discussed.

The paper is organised in the following way: the ALICE sub-systems used in the analysis are described in Section 2 and the data samples, event and track selection in Section 3. Section 4 describes the analysis methods and the systematic uncertainties are discussed in Section 5. Results are presented in Section 6 and conclusions are drawn in Section 7. The key results of the presented analysis are also reported in a short companion paper [23].

2 Experimental setup

A detailed description of the ALICE detector can be found in Ref. [24]. The main subsystems used in the present analysis are the Inner Tracking System (ITS) and the Time Projection Chamber (TPC). These have a common acceptance of $|\eta| < 0.9$ and are operated inside a solenoidal magnetic field of 0.5 T. The ITS consists of six layers of silicon detectors for vertex finding and tracking. The two outermost layers of the ITS constitute of the Silicon Strip Detectors (SSD), the two middle layers of the Silicon Drift Detectors (SDD) and the two innermost layers of the Silicon Pixel Detector (SPD) with the latter also used for triggering. The TPC is the main tracking detector measuring up to 159 space points per track. The V0 detector, consisting of two arrays of 32 scintillator tiles each, and covering $2.8 < \eta < 5.1$ (V0-A) and $-3.7 < \eta < -1.7$ (V0-C), was used for triggering and centrality determination [25, 26]. All these detector systems have full azimuthal coverage.

Data from the 2010 and 2011 Pb–Pb runs of the LHC at $\sqrt{s_{NN}} = 2.76$ TeV and the 2011 pp run at the same energy are combined in the present analysis. From the 2010 sample, about 16 million minimum-bias Pb–Pb events are considered, while in the 2011 Pb–Pb run about 2 million minimum-bias events and about 21 million centrality-triggered events enhancing the 0–50% centrality range are used. The pp event sample consists of 30 million minimum-bias events.

In Pb–Pb collisions, the trigger required a coincidence of signals in both V0-A and V0-C. In addition, two Zero Degree Calorimeters (ZDCs) for neutron detection located at $\pm 114$ m from the interaction point are used to suppress electromagnetic interactions. More details about the event selection can be found in Ref. [27]. The events are characterized into five collision-centrality classes based on the sum of amplitudes in the V0 detectors [25] (0–10% (most central), 10–20%, 20–30%, 30–50% and 50–80%). In pp collisions, the trigger required a signal in either of the V0 detectors or the SPD [28]. In both collision systems, these triggers are fully efficient for events entering the two-particle correlation analysis presented in this work.
3 Event and track selection

The collision-vertex position is determined with tracks reconstructed in the ITS and TPC as described in Ref. [1]. The vertex reconstruction algorithm is fully efficient for events with at least one reconstructed primary track within $|\eta| < 1.4$ [29]. The position of the reconstructed vertex along the beam direction ($z_{\text{vtx}}$) is required to be within 7 cm of the detector centre. This value is reduced to 3 cm in the study of systematic uncertainties.

The analysis uses tracks reconstructed in the ITS and TPC with $1 < p_T < 8$ GeV/$c$ and in a fiducial region of $|\eta| < 0.8$. As a first step in the track selection, criteria on the number of space points (at least 70) and the quality of the track fit ($\chi^2/\text{ndf} < 2$) in the TPC are applied. Tracks are further required to have a distance of closest approach to the reconstructed vertex smaller than 2.4 cm and 3.2 cm in the transverse and the longitudinal direction, respectively. Two classes of tracks are combined in order to avoid an azimuthally-dependent tracking efficiency due to inactive SPD modules [30]. The first class requires for tracks to have at least one hit in the SPD. For tracks which do not fulfil this criterion, in the second class, the primary vertex position is used as additional constraint in the global track fit. An alternative track selection [31], where a tighter $p_T$-dependent cut on the distance of closest approach to the reconstructed vertex is applied, is used for the assignment of a systematic uncertainty. Further, the tracks in the second class are required to have a hit in the first layer of the SDD. This modified selection has a less uniform azimuthal acceptance, but includes a smaller number of secondary particles produced by interactions in the detector material or weak decays.

The efficiency and purity of the primary charged-particle selection are estimated from a Monte Carlo (MC) simulation using the HIJING 1.383 event generator [32] (for Pb–Pb) and the PYTHIA 6.4 event generator [33] with the tune Perugia-0 [34] (for pp) with particle transport through the detector carried out with GEANT3 [35]. The combined efficiency and acceptance of the track reconstruction in $|\eta| < 0.8$ is about 82–85% at $p_T = 1$ GeV/$c$ and decreases to about 76–80% at $p_T = 8$ GeV/$c$ depending on collision system, data sample and event centrality. The contamination from secondary particles resulting from weak decays and due to interactions in the detector material decreases from 2.5–4.5% to 0.5–1% in the $p_T$ range from 1 to 8 GeV/$c$. The contribution from fake tracks, arising from improperly associated hits, is negligible. The alternative track selection (see above), has 3–6% lower combined efficiency and acceptance and about two thirds of the secondary contamination.

Due to the combination of different event samples, see Sec. 2, the number of accepted events per centrality class is not uniform, as is shown in Table 1.

4 Analysis

The correlation between two charged particles (denoted trigger and associated particle) is measured as a function of the azimuthal angle difference $\Delta\phi$ (defined within $-\pi/2$ and $3\pi/2$) and pseudorapidity difference $\Delta\eta$ [36]. The correlation is expressed in terms of the associated yield per trigger particle

| Collision system | Centrality class | Accepted events ($10^6$) |
|------------------|-----------------|--------------------------|
| Pb–Pb            | 0–10%           | 7.7                      |
|                  | 10–20%          | 2.9                      |
|                  | 20–30%          | 2.9                      |
|                  | 30–50%          | 5.9                      |
|                  | 50–80%          | 3.9                      |
| pp               | —               | 24.0                     |

Table 1: Centrality classes and corresponding number of accepted events in pp and Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 2.76$ TeV used in this analysis.
for intervals of trigger and associated transverse momentum, $p_{T,\text{trig}}$ and $p_{T,\text{assoc}}$, respectively. The $p_T$ intervals can be different or identical, in which case only pairs of particles with $p_{T,\text{assoc}} < p_{T,\text{trig}}$ are considered to avoid double counting. The per-trigger yield can be measured experimentally if the particle distribution is independent of pseudorapidity $\eta$ in the following way:

$$\frac{1}{N_{\text{trig}}} \frac{d^2N_{\text{assoc}}}{d\Delta \eta d\Delta \phi} = \frac{S(\Delta \eta, \Delta \phi)}{B(\Delta \eta, \Delta \phi)}$$

(1)

where $N_{\text{trig}}$ is the total number of trigger particles in the centrality class and $p_{T,\text{trig}}$ interval, ranging from 0.18 to 36 per event. The signal distribution $S(\Delta \eta, \Delta \phi) = 1/N_{\text{trig}} d^2N_{\text{same}}/d\Delta \eta d\Delta \phi$ is the associated yield per trigger particle for particle pairs from the same event. The background distribution $B(\Delta \eta, \Delta \phi) = \alpha d^2N_{\text{mixed}}/d\Delta \eta d\Delta \phi$ corrects for finite pair acceptance and pair efficiency. It is constructed by correlating the trigger particles in one event with the associated particles from other events in the same centrality class and within the same 2 cm-wide $z_{\text{vtx}}$ interval (each event is mixed with 5–20 events depending on the number of tracks per event). The background distribution is scaled by a factor $\alpha$ which is chosen such that $B(0, 0)$ is unity for pairs where both particles travel in approximately the same direction (i.e. $\Delta \phi \approx 0$, $\Delta \eta \approx 0$), and thus the efficiency and acceptance for the two particles are identical by construction. The yield defined by Eq. (1) is constructed for each $z_{\text{vtx}}$ interval to account for differences in pair acceptance and efficiency, depending on the vertex position $z_{\text{vtx}}$. The trigger particles and the pairs are corrected for single-particle efficiency, described below, before the final per-trigger yield is obtained by calculating the average of the $z_{\text{vtx}}$ intervals weighted by $N_{\text{trig}}$.

A minimum opening angle of the particle pairs is required for both signal and background to avoid a bias due to the reduced efficiency for pairs with small separation. Pairs are required to have a separation of $|\Delta \phi_{\text{min}}| > 0.02$ rad or $|\Delta \eta| > 0.02$, where $\Delta \phi_{\text{min}}$ is the minimal azimuthal distance at the same radius between the two tracks within the active detector volume after accounting for the bending in the magnetic field. Furthermore, correlations induced by secondary particles from long-lived neutral-particle decays ($K_S^0$ and $\Lambda$) and $\gamma$-conversions are suppressed by cutting on the invariant mass ($m_{\text{inv}}$) of the particle pair. Pairs are removed which are likely to stem from a $\gamma$-conversion ($m_{\text{inv}} < 4 \text{ MeV}/c^2$), a $K_S^0$ decay ($|m_{\text{inv}} - m(K_S^0)| < 5 \text{ MeV}/c^2$) or a $\Lambda$ decay ($|m_{\text{inv}} - m(\Lambda)| < 5 \text{ MeV}/c^2$). Weak decays of heavier particles give a negligible contribution.

Each trigger and each associated particle is weighted with a correction factor that accounts for detector acceptance, reconstruction efficiencies and contamination from secondary particles. These corrections are applied as a function of $\eta$, $p_T$, $z_{\text{vtx}}$ and event centrality. The shape parameters extracted below are expected to be insensitive to these single-particle corrections which was confirmed in the analysis.

The obtained per-trigger yields as a function of relative angle are integrated over particles produced within $|\eta| < 0.8$. As mentioned above, the method requires that the distribution of sources contributing to the correlation are independent of pseudorapidity, which is approximately the case for the inclusive particle distribution [25] as well as the anisotropic flow [38]. A dependence on pseudorapidity results in distortions as a function of $\Delta \eta$ of the per-trigger yields which are independent of $\Delta \phi$. In addition, the finite bin width in the event mixing has been found to cause $\Delta \eta$-dependent effects. Distortions in $\Delta \eta$, of the order of 0.1%, have been observed and are attributed to the residual slight dependence of inclusive particle distribution and anisotropic flow on $\eta$. While small, these distortions are still relevant compared to the jet-like peak which is on top of the large combinatorial background. In order to suppress distortions of the peak in the $\Delta \eta$ direction, a correction factor is calculated such that the away side becomes independent of $\Delta \eta$ and is applied to all $\Delta \phi$ bins.

In order to characterize the near-side peak shape, a simultaneous fit of the peak, the combinatorial background and the long-range correlation background stemming from collective effects is performed. This exploits that in two-particle correlations the near-side peak is centred around $\Delta \phi = 0$, $\Delta \eta = 0$ while long-range correlation structures are approximately independent of $\Delta \eta$ [38]. This strategy limits the analysis...
Evolution of the longitudinal and azimuthal structure . . .

ALICE Collaboration

Fig. 1: Illustration of the fitting procedure for the 10% most central Pb–Pb events at √s_{NN} = 2.76 TeV in 2 < p_{T,assoc} < 3 GeV/c and 3 < p_{T, trig} < 4 GeV/c. The panels show (a) the two-dimensional azimuthal and pseudorapidity total per-trigger yield, (b) the background distribution and (c) the signal peak component from the fit by Eq. 2, and (d) the relative difference between the data and the fit.

To the near side, as the away-side peak is elongated in Δη. The fit function used is a combination of a constant, a generalized two-dimensional Gaussian function and cos(nΔφ) terms for n = 2, 3, 4.

\[ F(Δφ, Δη) = C_1 + \sum_{n=2}^{4} 2 V_{nΔ} \cos(nΔφ) + C_2 \cdot G_{γ_{Δφ}, w_{Δφ}}(Δφ) \cdot G_{γ_{Δη}, w_{Δη}}(Δη) \]  

\[ G_{γ, w}(x) = \frac{γ}{2 w \Gamma(1/γ)} \exp \left[ - \left( \frac{|x|}{w} \right)^γ \right] \]

Thus, in Pb–Pb collisions, the background is characterized by 4 parameters (C_1, V_{nΔ}) where V_{nΔ} are the Fourier components of the long-range correlations [39], and it should be noted that the inclusion of orders higher than 4 does not significantly change the fit results. In pp collisions, however, the background consists effectively only of the pedestal C_1. The peak magnitude is characterized by C_2, and the shape which is the focus of the present analysis by 4 parameters (γ_{Δφ}, w_{Δφ}, γ_{Δη}, w_{Δη}). Note that for γ = 2
the generalized Gaussian function $G$ is a Gaussian, and for $\gamma = 1$ it is a Laplace distribution, which is an exponential where the absolute value of the argument is taken (exp(−|x|)). The aim of using this fit function is to allow for a compact description of the data rather than attempting to give a physical meaning to each parameter. A further reduced description of the peak shape is provided by the variances ($\sigma_{\Delta \phi}$ and $\sigma_{\Delta \eta}$) of the generalized Gaussian. The evolution of the peak shape from peripheral to central collisions is described by the ratio of the width in the central bin (0–10%) and the peripheral bin (50–80%), denoted by $\sigma_{\Delta \phi}^{CP}$ and $\sigma_{\Delta \eta}^{CP}$.

In the data, a depletion around $\Delta \phi = 0$, $\Delta \eta = 0$ is observed at low $p_T$, however, the fit function does not include such a depletion. Several bins in the central region are excluded from the fit avoiding a bias on the extracted peak width. The size of the excluded region varies with $p_T$ and centrality (from no exclusion to 0.3). Thus, by definition, the peak width describes the shape of the peak outside of the central region. The depletion in the central region is quantified by the near-side depletion yield in Section 6.3 by computing the difference between the fit and the per-trigger yield within the exclusion region.

Figure 1 illustrates the fit procedure. Shown is the data as well as the background and peak components of the fit. The bottom right panel shows the difference between the data and the fit where only minor deviations less than 0.5% can be observed. Figure 2 shows the $\Delta \phi$ and $\Delta \eta$ projections of the data overlaid with the obtained fit functions. The comparison with the background illustrates the magnitude of the peak.

In Pb–Pb collisions, the $\chi^2$/ndf values of the fits are found in the range 1.0–2.5; most are around 1.5. In the highest two $p_T$ bins (i.e. in $3 < p_{T,\text{assoc}} < 8$ GeV/$c$ and $4 < p_{T,\text{trig}} < 8$ GeV/$c$) the values increase up to about 2.5 showing that at high $p_T$ the peak shape starts to depart from the generalized Gaussian description. In pp collisions, the $\chi^2$/ndf values are in the range 1.3–2.0.

Different fitting strategies have been tried using a two-dimensional Gaussian to describe the peak, which is found to not describe the data satisfactorily (conversely, the $\chi^2$/ndf is too large). A superposition of two two-dimensional Gaussians describes the data well, but is found unstable compared to the generalized Gaussian. In general, the fit with a single two-dimensional Gaussian results in smaller peak widths than the generalized Gaussian case which in turn has smaller peak widths than the two two-dimensional Gaussian fit.

Table 2: Summary of the systematic uncertainties of the analysis. Ranges indicate a dependence on centrality.

5 Systematic uncertainties

Systematic uncertainties connected to the measurement are determined modifying the selection criteria discussed above and repeating the analysis. The difference in the extracted parameters is studied as a function of $p_T$, centrality and collision system, but these dependencies are rather weak and one uncertainty value can be quoted for each source of systematic uncertainty in most cases. Finally, the contribution from the different sources of systematic uncertainties are added in quadrature. The extracted peak widths are rather insensitive to changes in the selections (total uncertainty of about 2–4.5%) while the near-side depletion yield defined in Sec. 6.3 is more sensitive (about 24–45% uncertainty).

Table 2 summarizes the different sources of systematic uncertainties which have been considered. Changes of vertex range and track selection have already been detailed in Sec. 3. The selection criterion on pairs with small opening angles (see Sec. 4) is increased by a factor 2 and the mass range in the cut removing neutral-particle decays is modified by 50%. The size of the exclusion region around $\Delta \phi = 0, \Delta \eta = 0$ (see Sec. 4) is enlarged by 0.17 (0.2) in the $\Delta \phi (\Delta \eta)$ direction. The sensitivity of the analysis results to the pseudorapidity range used is assessed by changing it by $\pm 0.1$. This uncertainty includes effects of the pseudorapidity dependence of the anisotropic flow as well as the particle production in general. No dependence of the results presented in this paper on the polarity of the magnetic field was observed.

The influence of resonance decays on the observations presented below were investigated by performing the analysis separately for like-sign and unlike-sign pairs. While the numerical values change, which is not unexpected, the qualitative conclusions presented below are unchanged. In particular, the reported broadening and depletion are larger in the like-sign case suggesting that resonance decays do not play a significant role for these phenomena.

6 Results

The top row of Fig. 3 shows the near-side peak in $1 < p_{T,\text{trig}} < 2 \text{ GeV}/c$ and $1 < p_{T,\text{assoc}} < 2 \text{ GeV}/c$ after subtraction of the background estimated with Eq. 2. The peak has a similar shape in pp collisions and in peripheral (50–80% centrality) Pb–Pb collisions, where it is approximately symmetric in $\Delta \phi$ and $\Delta \eta$. In the 10% most central collisions a different picture is observed: the near-side peak is broader than in peripheral collisions and wider in $\Delta \eta$ than in $\Delta \phi$. Furthermore, a depletion around $\Delta \phi = 0, \Delta \eta = 0$ develops which will be discussed in more detail further below. At higher $p_T$ (bottom row of Fig. 3), the near-side peak is also found broader in central collisions than in peripheral or pp collisions, although it is visually less pronounced, but the asymmetry between $\Delta \phi$ and $\Delta \eta$ disappears at the two highest $p_T$ bins included in the analysis. In addition, the amplitude of the peak is smaller in central collisions. Figure 4 shows the projections of the two-dimensional histogram shown in Fig. 3(c) where the depletion is largest, together with the fitted function.
Evolution of the longitudinal and azimuthal structure ... ALICE Collaboration

Fig. 3: Associated yield per trigger particle as a function of $\Delta \varphi$ and $\Delta \eta$ in pp collisions (left panels) and Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV in the 50–80% centrality class (middle panels) and in the 0–10% centrality class (right panels). The top row shows $1 < p_{T,\text{assoc}} < 2$ GeV/c and $1 < p_{T,\text{trig}} < 2$ GeV/c and the bottom row shows $2 < p_{T,\text{assoc}} < 3$ GeV/c and $3 < p_{T,\text{trig}} < 4$ GeV/c. The background obtained from the fit function has been subtracted in order to emphasize the near-side peak.

Fig. 4: Projections of Fig. 3(c) to the $\Delta \varphi$ (a) and $\Delta \eta$ (b) directions, the depletion around $\Delta \varphi = 0$, $\Delta \eta = 0$ is clearly visible in both directions.
6.1 Peak widths

We examine and quantify the evolution of the near-side peak shape and width with the fit procedure described in Sec. 4. The extracted shape parameters $\sigma_{\Delta \phi}$ and $\sigma_{\Delta \eta}$ are presented in Fig. 5. In pp collisions, the $\sigma$ values range from 0.14 to 0.43 showing the expected $p_T$ dependence: due to the boost of the evolving parton shower at larger $p_T$ the peak is narrower. In the $\Delta \phi$ direction (left panel) the values obtained in pp collisions are consistent with those in peripheral Pb–Pb collisions. The peak width increases towards central events which is most pronounced in the lowest $p_T$ bin (20% increase). In the higher $p_T$ bins no significant width increase can be observed. In the $\Delta \eta$ direction (right panel) a much larger broadening towards central collisions is found. Already in peripheral collisions the width is larger than in pp collisions, and from peripheral to central collisions the width increases further up to $\sigma_{\Delta \eta} = 0.67$ in the lowest $p_T$ bin. The largest relative increase of about 85% is observed for $2 < \rho_{T,\text{trig}} < 3 \text{ GeV/c}$ and $2 < \rho_{T,\text{assoc}} < 3 \text{ GeV/c}$. A significant broadening can be observed for all but the two largest $p_T$ bins. This increase is quantified for all $p_T$ bins in Fig. 6 by $\sigma_{\Delta \phi}^c$ and $\sigma_{\Delta \eta}^c$. The increase is quantified with respect to peripheral Pb–Pb instead of pp to facilitate the MC comparisons discussed below.

In pp collisions, the peak shows circular symmetry in the $\Delta \eta$–$\Delta \phi$ plane for all $p_T$. In Pb–Pb collisions, the peak becomes asymmetric towards central collisions for all but the two highest $p_T$ bins. The magnitude of this asymmetry depends on $p_T$ and is largest with about 70% ($\sigma_{\Delta \eta} > \sigma_{\Delta \phi}$) in the range $2 < \rho_{T,\text{trig}} < 3 \text{ GeV/c}$ and $2 < \rho_{T,\text{assoc}} < 3 \text{ GeV/c}$.

6.2 Model comparison

The interplay of longitudinal flow with a fragmenting high $p_T$ parton was suggested in Ref. [19] as a possible source for the observed asymmetric peak shape. The authors argue that hard partons are interacting with a medium which shows collective behaviour. This is confronted with the simpler picture where the parton propagates through an isotropic medium with respect to the parton direction. In their calculation the scattering centres are Lorentz-boosted by applying a momentum shift depending on the collective component transverse to the parton-propagation direction. The calculation in Ref. [19] for
Evolution of the longitudinal and azimuthal structure … ALICE Collaboration

Fig. 6: Ratio of the peak widths in $\Delta \phi$ (left panel) and $\Delta \eta$ (right panel) observed in central (0–10%) and peripheral (50–80%) collisions as a function of $p_{T,\text{trig}}$ and $p_{T,\text{assoc}}$ ranges. The data is compared to the different AMPT settings. Note that the $x$-axis combines the $p_{T,\text{assoc}}$ and $p_{T,\text{trig}}$ axis, and therefore, a uniform trend of the values is not expected. Lines indicate statistical uncertainties (mostly smaller than the marker size), while boxes (only for data) denote systematic uncertainties.

Au–Au collisions at $\sqrt{s_{\text{NN}}}=200$ GeV expects a 20% increase from peripheral to central events for the $\Delta \phi$ direction and a 60% increase for the $\Delta \eta$ direction. Despite the different centre-of-mass energy and collision system, the calculation is in quantitative agreement with the results presented in this paper.

Further studies on the possibility that the effect can be caused by an interplay of flow and jets have been done comparing the data to generator-level results from A Multi-Phase Transport model (AMPT) [40, 41] which has been shown to feature a longitudinal broadening of the near-side peak [42]. Two mechanisms in AMPT produce collective effects: partonic and hadronic rescattering. Before partonic rescattering, the initially produced strings may be broken into smaller pieces by the so-called string melting. Three different AMPT settings are considered, having either string melting or hadronic rescattering or both activated. About 10 million events were generated for each of the cases with string melting activated, and about 47 million events for the case with string melting disabled. The results obtained in pp collisions are compared to PYTHIA 8.1 simulations [44] with the Monash tune [45] with about 500 million generated events.

The peak widths and $\sigma_{\Delta \phi}^{\text{CP}}$ and $\sigma_{\Delta \eta}^{\text{CP}}$ are extracted from particle level AMPT simulations in the same way as for the data. Figure 6 compares these ratios to the data. In the $\Delta \phi$ direction, the setting with string melting deactivated and hadronic rescattering active follows the trend of the data closest. The two other settings show a more uniform distribution across $p_T$ and only differ in the two lowest $p_T$ bins. In the $\Delta \eta$ direction, the setting with string melting deactivated and hadronic rescattering active quite remarkably follows the trend of the data including the large increase for intermediate $p_T$. The two other settings show qualitatively a similar trend but miss the data quantitatively.

In addition to the relative increase, it is interesting to compare the absolute widths. Figure 7 presents the ratio of the widths measured in Pb–Pb collisions to the three AMPT settings as well as the ones

---

1AMPT versions v1.25t3 (without string melting, parameter isoft = 1) and v2.25t3 (with string melting, parameter isoft = 4) are used. In addition, in one sample the use of rescattering in the hadronic phase is disabled by setting the parameter ntmax to 3 (the default is 150). See Ref. [43] for more details on these settings.
measured in pp collisions to PYTHIA simulations with the Monash tune. In general, none of the AMPT settings provides an accurate description of the data. The setting which matches best the relative width increase (string melting deactivated, hadronic rescattering active), overestimates the width by on average 20–30% with a mild $p_T$ dependence. The two settings with string melting show a decreasing (increasing) trend as a function of $p_T$ in central (peripheral) collisions in the $\Delta \phi$ direction. In the $\Delta \eta$ direction, in central collisions, they both over- and underestimate the data depending on $p_T$, while there is about 10% overestimation in peripheral collisions mostly independent of $p_T$. The width in pp collisions is well described by PYTHIA at high $p_T$ in both directions, while the width in $\Delta \phi$ ($\Delta \eta$) is overestimated by 10% (25%) at low $p_T$.

6.3 Near-side depletion

The results presented in the previous section have focused on the overall shape of the near-side peak. In addition to the broadening, a distinct feature in central collisions and at the low $p_T$ is observed, a depletion around $\Delta \phi = 0$, $\Delta \eta = 0$ (top right panel of Fig. 3 and Fig. 4).

An extensive set of studies was carried out to determine whether this depletion could arise from detector
higher $p$ observed for 50–80% (30–80%) centrality or pp collisions for the lowest (second lowest) $p$ central events. This value decreases gradually with centrality and with $p$ function of centrality for the $p$ 6% of the integrated region) is excluded from this calculation. Fig. 9 presents the depletion yield as a function of $\Delta \phi$ and $\Delta \eta$ in AMPT (generator level) for the $|\Delta \eta| < 1.6$ region. A splitting of a particle’s trajectory into two tracks may cause distortions of the two-particle correlation in parts of the detector volume may suffer from efficiency losses and reconstruction imperfections, e.g. a splitting of a particle’s trajectory into two tracks may cause distortions of the two-particle correlation around $\Delta \phi = 0$, $\Delta \eta = 0$. It was shown that such detector-related effects are present but only in a very limited region of where both $|\Delta \phi|$ and $|\Delta \eta|$ are smaller than 0.04–0.05. The depletion discussed in this section extends out to $|\Delta \eta|$ well beyond 0.3 which is significantly larger than the detector resolution and the reach of two-track efficiency effects. A detector-related origin is thus excluded.

Figure 8 presents the per-trigger yield and their projections to the $\Delta \phi$ and $\Delta \eta$ axes for the AMPT simulations in the same $p_T$ and centrality bin as the top panel of Fig. 3. The AMPT simulations with hadronic rescattering show a depletion regardless of the string melting setting.

In order to quantify this depletion, the difference between the fit (where the depletion region has been excluded, see above) and the per-trigger yield relative to the total peak yield for the $p_T$ bins is computed and this is referred to as depletion yield in the following. The region where effects are expected from the limited two-track reconstruction efficiency ($|\Delta \phi| < 0.04$ and $|\Delta \eta| < 0.05$, which corresponds to 0.5–6% of the integrated region) is excluded from this calculation. Fig. 8 presents the depletion yield as a function of centrality for the $p_T$ bins where it is different from 0. It can be seen that (2.2±0.5)% of the yield is missing in the lowest $p_T$ bin $(1 < p_{T,\text{trig}} < 2 \text{ GeV/c}, 1 < p_{T,\text{assoc}} < 2 \text{ GeV/c})$ and in the 10% most central events. This value decreases gradually with centrality and with $p_T$. No significant depletion is observed for 50–80% (30–80%) centrality or pp collisions for the lowest (second lowest) $p_T$ range. For higher $p_T$ bins, no significant depletion is observed.
Fig. 9: Missing yield in the depletion region relative to the overall peak yield extracted from the fit. Lines indicate statistical uncertainties (mostly smaller than the marker size), while boxes (only for data) denote systematic uncertainties. The arrows indicate the upper limit in case the uncertainty bands touch 0. The markers are placed at the centre of the centrality bins. For comparison, the non-zero values from two AMPT simulations are shown as lines.

The depletion observed in the AMPT events is present only in the lowest $p_T$ bin, where its value is compatible with the data for both settings where hadronic rescattering is switched on. For larger $p_T$ bins and for the configuration without hadronic rescattering the depletion yield is consistent with 0 in AMPT.

6.4 Relation to radial and elliptic flow

In order to put the observations in context with the strength of radial and anisotropic flow, Table 3 presents the radial-flow expansion velocity $\beta_T$ and the elliptic flow coefficient $v_2 \{2 \}$ for the 10% most central events from data (from [46, 47]) and from the AMPT samples. The expansion velocity $\beta_T$ is extracted from a Blast-Wave fit to the $p_T$-spectra of $\pi$, K and p in the range of $0.5 < p_T < 1$ GeV/c, $0.2 < p_T < 1.5$ GeV/c and $0.3 < p_T < 2$ GeV/c, respectively, and in the rapidity range of $|y| < 0.5$. The fit describes the AMPT simulation with 10% precision in the fitted range (see Ref. [46] for details on the fitting procedure). The $v_2 \{2 \}$ is extracted from two-particle correlations within $|\eta| < 0.8$ and $0.2 < p_T < 5$ GeV/c (see Ref. [47] for details on the procedure).

| Sample                                      | $\beta_T$   | $v_2 \{2 \}$               |
|---------------------------------------------|-------------|-----------------------------|
| AMPT string melting and hadronic rescattering | 0.442       | 0.0412 ± 0.00002            |
| AMPT string melting                         | 0.202       | 0.0389 ± 0.00002            |
| AMPT hadronic rescattering                  | 0.540       | 0.0330 ± 0.00002            |
| Data                                        | 0.649 ± 0.022 | 0.0364 ± 0.00003          |

Table 3: Blast-wave fit parameter $\beta_T$ and elliptic flow coefficient $v_2 \{2 \}$ for 0–10% centrality in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV in the considered AMPT samples and for comparison in the data (from [46, 47]). Uncertainties are statistical for the MC samples and combined statistical and systematic ones for the data. The statistical uncertainties for the Blast-wave fits on AMPT are negligible.

The radial-flow expansion velocity $\beta_T$ is larger when hadronic rescattering is active and largest if in addition string melting is switched off, while the configuration without hadronic rescattering results in a low $\beta_T$. The value found in the data is about 20% larger than the highest one in the AMPT simulations. The elliptic flow coefficient $v_2 \{2 \}$ is better described by AMPT. Closest are the configurations
with either string melting or hadronic rescattering (about 7% discrepancy), while the configuration with both processes simultaneously overestimates the $v_2 \{2\}$. The differences between the different AMPT configurations are much smaller for the elliptic flow than for the radial flow.

The depletion discussed in the previous section occurs in the two AMPT configurations where the $\beta_T$ is large, while the configuration without the depletion has the smallest $\beta_T$. The coefficient $v_2 \{2\}$ has significantly different values in the two configurations with depletion, and the relative increase of the peak width (Fig. 6) is best described by the AMPT configuration with the largest $\beta_T$. These studies suggest that the radial flow is more likely responsible for the depletion than the elliptic flow.

Ref. [42] studied partonic pseudorapidity distributions at different evolution times in AMPT. The authors show that the longitudinal broadening is driven by large values of longitudinal flow. In a picture where expansion is driven by pressure gradients, strong radial expansion can be accompanied by large longitudinal expansion. In conclusion, in AMPT, the observed phenomena are related to large values of radial and longitudinal flow.

### 6.5 Comparison to other experiments

The STAR collaboration has studied near-side peak shapes at $\sqrt{s_{NN}} = 62.4$ GeV and $\sqrt{s_{NN}} = 200$ GeV in d–Au, Cu–Cu and Au–Au collisions [14]. Apart from the peak width quantification, done separately in the $\Delta \eta$ and $\Delta \phi$ direction with one-dimensional Gaussian functions after the subtraction of the background, the analysis method is compatible to the one presented in this analysis. In the studies presented in this paper, it was found that the peak widths with one two-dimensional Gaussian lead generally to smaller values than with the generalized Gaussian, and the fit quality is not optimal for the large statistics collected at the LHC. However, despite the difference in centre-of-mass energy, the larger statistical uncertainties in the analysis reported by the STAR collaboration may have hidden the possibility that the generalized Gaussian is a better description of the near-side peak.

The STAR collaboration also observed a broadening of the peak widths from peripheral to central collisions at $\sqrt{s_{NN}} = 200$ GeV in Au–Au collisions. The effect is most significant for $2 < p_{T,assoc} < 4$ GeV/c.
In the $\Delta \phi$ direction, the width increases by 25–30% depending on the $p_T$, and in the $\Delta \eta$ direction, the increase is about 40–60%. This effect is comparable to the observations presented in this paper. Figure 10 compares the results in the centrality bins which have the largest overlap between the two experiments. Agreement between the STAR results and this work is observed, within statistical uncertainties, in all overlapping momentum and centrality bins, with the exception of central collisions in the $\Delta \phi$ direction, where a two-sigma difference can be seen.

7 Summary

We have presented a detailed characterization of the flow-subtracted near-side peak in two-particle correlations in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV together with a measurement in pp collisions at the same energy. The near-side peak shows the characteristic $p_T$ dependence, where the width decreases with increasing $p_T$. In addition, in Pb–Pb collisions a centrality dependence is observed: the peak gets wider from peripheral to central collisions. This effect is significantly stronger for the $\Delta \eta$ direction than for the $\Delta \phi$ direction leading to an asymmetric peak shape in central collisions, observed over a wide $p_T$ range. Additionally, at low $p_T$, an unexpected depletion develops from peripheral to central collisions.

AMPT simulations show that both the asymmetric broadening and the depletion are also present when hadronic rescattering is included. The AMPT configuration with hadronic rescattering and without string melting reproduces quantitatively the relative peak broadening as well as the size of the depletion. The extraction of the radial-flow expansion velocity suggests that the stronger the radial flow, the stronger the observed effects are. In addition, earlier theoretical and phenomenological work connected the longitudinal broadening of the near-side jet-like peak to strong longitudinal flow in AMPT, as well as to an interplay of partons traversing the longitudinally expanding medium. Thus a possible scenario is that the presented observations are caused by the interplay of the jet with the collective expansion.

Acknowledgements

The ALICE Collaboration would like to thank all its engineers and technicians for their invaluable contributions to the construction of the experiment and the CERN accelerator teams for the outstanding performance of the LHC complex. The ALICE Collaboration gratefully acknowledges the resources and support provided by all Grid centres and the Worldwide LHC Computing Grid (WLCG) collaboration. Affiliation notes

1 Deceased
2 Also at: Georgia State University, Atlanta, Georgia, United States
3 Also at: Also at Department of Applied Physics, Aligarh Muslim University, Aligarh, India
4 Also at: M.V. Lomonosov Moscow State University, D.V. Skobeltsyn Institute of Nuclear Physics, Moscow, Russia

Collaboration Institutes

1 A.I. Alikhanyan National Science Laboratory (Yerevan Physics Institute) Foundation, Yerevan, Armenia
2 Benemérita Universidad Autónoma de Puebla, Puebla, Mexico
3 Bogolyubov Institute for Theoretical Physics, Kiev, Ukraine
4 Bose Institute, Department of Physics and Centre for Astroparticle Physics and Space Science (CAPPS), Kolkata, India
5 Budker Institute for Nuclear Physics, Novosibirsk, Russia
6 California Polytechnic State University, San Luis Obispo, California, United States
7 Central China Normal University, Wuhan, China
8 Centre de Calcul de l’IN2P3, Villeurbanne, Lyon, France
9 Centro de Aplicaciones Tecnológicas y Desarrollo Nuclear (CEADEN), Havana, Cuba
Evolution of the longitudinal and azimuthal structure . . . ALICE Collaboration

10Centro de Investigaciones Energéticas Medioambientales y Tecnológicas (CIEMAT), Madrid, Spain
11Centro de Investigación y de Estudios Avanzados (CINVESTAV), Mexico City and Mérida, Mexico
12Centro Fermi - Museo Storico della Fisica e Centro Studi e Ricerche “Enrico Fermi”, Rome, Italy
13Chicago State University, Chicago, Illinois, United States
14China Institute of Atomic Energy, Beijing, China
15Commissariat à l’Energie Atomique, IRFU, Saclay, France
16COMSATS Institute of Information Technology (CIIT), Islamabad, Pakistan
17Departamento de Física de Partículas and IGFAE, Universidad de Santiago de Compostela, Santiago de Compostela, Spain
18Department of Physics, Aligarh Muslim University, Aligarh, India
19Department of Physics, Ohio State University, Columbus, Ohio, United States
20Department of Physics, Sejong University, Seoul, South Korea
21Department of Physics, University of Oslo, Oslo, Norway
22Department of Physics and Technology, University of Bergen, Bergen, Norway
23Dipartimento di Fisica dell’Università ‘La Sapienza’ and Sezione INFN, Rome, Italy
24Dipartimento di Fisica dell’Università and Sezione INFN, Cagliari, Italy
25Dipartimento di Fisica dell’Università and Sezione INFN, Trieste, Italy
26Dipartimento di Fisica dell’Università and Sezione INFN, Turin, Italy
27Dipartimento di Fisica e Astronomia dell’Università and Sezione INFN, Bologna, Italy
28Dipartimento di Fisica e Astronomia dell’Università and Sezione INFN, Catania, Italy
29Dipartimento di Fisica and Astronomia dell’Università and Sezione INFN, Padova, Italy
30Dipartimento di Fisica ‘E.R. Caianiello’ dell’Università and Gruppo Collegato INFN, Salerno, Italy
31Dipartimento DISAT del Politecnico and Sezione INFN, Turin, Italy
32Dipartimento di Scienze e Innovazione Tecnologica dell’Università del Piemonte Orientale and INFN Sezione di Torino, Alessandria, Italy
33Dipartimento Interateneo di Fisica ‘M. Merlin’ and Sezione INFN, Bari, Italy
34Division of Experimental High Energy Physics, University of Lund, Lund, Sweden
35European Organization for Nuclear Research (CERN), Geneva, Switzerland
36Excellence Cluster Universe, Technische Universität München, Munich, Germany
37Faculty of Engineering, Bergen University College, Bergen, Norway
38Faculty of Mathematics, Physics and Informatics, Comenius University, Bratislava, Slovakia
39Faculty of Nuclear Sciences and Physical Engineering, Czech Technical University in Prague, Prague, Czech Republic
40Faculty of Science, P.J. Šafárik University, Košice, Slovakia
41Faculty of Technology, Buskerud and Vestfold University College, Tonsberg, Norway
42Frankfurt Institute for Advanced Studies, Johann Wolfgang Goethe-Universität Frankfurt, Frankfurt, Germany
43Gangneung-Wonju National University, Gangneung, South Korea
44Gauhati University, Department of Physics, Guwahati, India
45Helmholtz-Institut für Strahlen- und Kernphysik, Rheinische Friedrich-Wilhelms-Universität Bonn, Bonn, Germany
46Helsinki Institute of Physics (HIP), Helsinki, Finland
47Hiroshima University, Hiroshima, Japan
48Indian Institute of Technology Bombay (IIT), Mumbai, India
49Indian Institute of Technology Indore, Indore, India
50Indonesian Institute of Sciences, Jakarta, Indonesia
51Inha University, Incheon, South Korea
52Institut de Physique Nucléaire d’Orsay (IPNO), Université Paris-Sud, CNRS-IN2P3, Orsay, France
53Institute for Nuclear Research, Academy of Sciences, Moscow, Russia
54Institute for Subatomic Physics of Utrecht University, Utrecht, Netherlands
55Institute for Theoretical and Experimental Physics, Moscow, Russia
56Institute of Experimental Physics, Slovak Academy of Sciences, Košice, Slovakia
57Institute of Physics, Academy of Sciences of the Czech Republic, Prague, Czech Republic
58Institute of Physics, Bhubaneswar, India
59Institute of Space Science (ISS), Bucharest, Romania
60Institut für Informatik, Johann Wolfgang Goethe-Universität Frankfurt, Frankfurt, Germany
61Institut für Kernphysik, Johann Wolfgang Goethe-Universität Frankfurt, Frankfurt, Germany
