ABSTRACT

We report on optical and near-infrared observations obtained during and after the 2004 December discovery outburst of the X-ray transient and accretion-powered millisecond pulsar IGR J00291+5934. Our observations monitored the evolution of the brightness and the spectral properties of IGR J00291+5934 during the outburst decay toward quiescence. We also present optical, near-infrared, and Chandra observations obtained during true quiescence. Photometry of the field during outburst reveals an optical and near-infrared counterpart that brightened from \( R \approx 23 \) to \( R \approx 17 \) and from \( K = 19 \) to \( K \approx 16 \). Spectral analysis of the \( R\)IJKH broadband photometry shows excess in the near-infrared bands that may be due to synchrotron emission. The \( H\alpha \) emission line profile suggests the orbital inclination is \( \approx 22^\circ \)–32\(^\circ\). The preferred range for the reddening toward the source is \( 0.7 \leq E(B-V) \leq 0.9 \), which is equivalent to \( 4.06 \times 10^{-1} \text{ cm}^{-2} \leq N_H \leq 5.22 \times 10^{21} \text{ cm}^{-2} \). The Chandra observations of the pulsar in its quiescent state gave an unabsorbed 0.5–10 keV flux for the best-fitting power-law model to the source spectrum of \( (7.0 \pm 0.9) \times 10^{-14} \text{ ergs cm}^{-2} \text{s}^{-1} \) (adopting a hydrogen column of \( 4.6 \times 10^{21} \text{ cm}^{-2} \)). The fit resulted in a power-law photon index of \( 2.4^{+0.5}_{-0.4} \). The \( (R-K) \) color observed during quiescence supports an irradiated donor star and accretion disk. We estimate a distance of \( 2-4 \text{ kpc} \) toward IGR J00291+5934 by using the outburst X-ray light curve and the estimated critical X-ray luminosity necessary to keep the outer parts of the accretion disk ionized. Using the quiescent X-ray luminosity and the spin period, we constrain the magnetic field of the neutron star to be \( < 3 \times 10^8 \text{ G} \).

1. INTRODUCTION

Most known pulsars are isolated neutron stars characterized by pulse (spin) periods of about 0.5 s that increase at a rate of \( \dot{P} = dP/dt \sim 10^{-15} \text{ s}^{-1} \) as the rotational kinetic energy is carried away by magnetic dipole radiation (see, e.g., Lorimer 2005 and references therein). This implies young neutron stars with characteristic ages of \( \tau = P/2\dot{P} \sim 10^7 \text{ yr} \) and a magnetic field strength of \( B \sim (P\dot{P})^{1/2} \sim 10^{12} \text{ G} \). However, a small fraction of this pulsar population has millisecond periods with rotation periods ranging from 1.5 s to 30 ms and \( \dot{P} \sim 10^{-10} \text{ s}^{-1} \). They are thought to be old neutron stars (\( \tau \sim 10^9 \text{ yr} \)) with magnetic fields of \( B \sim 10^{8-10} \text{ G} \). Binary evolution theory predicts that millisecond pulsars are spun up during mass transfer from the companion star onto the neutron star during the low-mass X-ray binary phase (see, e.g., Alpar et al. 1982; Radhakrishnan & Srinivasan 1982; Bhattacharya & van den Heuvel 1991). This prediction agrees with the wealth of millisecond pulsars found in binary systems (~80% of the current sample compared to \( \leq 1% \) of the young pulsars). In addition, eight low-mass X-ray binaries have been found (to date) to harbor an accretion-driven millisecond X-ray pulsar (see, e.g., Wijnands 2005). All eight were discovered as X-ray transients when they underwent an outburst caused by an episode of intense mass transfer onto the neutron star via an accretion disk.

The accretion-driven millisecond X-ray pulsar IGR J00291+5934 was first detected in outburst on 2004 December 2 during Galactic plane scans with INTEGRAL (Eckert et al. 2004). Re-analysis of the Rossi X-Ray Timing Explorer (RXTE) All-Sky Monitor (ASM) data archive showed that the source was likely active during 1998 November and 2001 September, leading to a tentative recurrence time of approximately 3 years (Remillard 2004). Follow-up observations with the RXTE Proportional Counter Array (PCA) revealed that IGR J00291+5934 (hereafter J00291) has a 147.4 minute binary orbit and harbors a neutron star spinning at 599 Hz (1.7 ms). To date this is the fastest neutron star spin observed for an accretion-powered X-ray pulsar (Markwardt et al. 2004a, 2004b).

Outburst spectra obtained by INTEGRAL and RXTE are consistent with an absorbed power law, yielding a photon index of \( \alpha \approx 1.7-1.8 \) and a hydrogen column density of \( \geq 2 \times 10^{21} \text{ cm}^{-2} \) (Shaw et al. 2005; Galloway et al. 2005). The INTEGRAL spectrum was also well fitted by a thermal Comptonization model with electron temperature of 50 keV and Thomson optical depth \( \approx 1 \) (Falanga et al. 2005; Shaw et al. 2005). In addition, the RXTE PCA data could be fitted with a two component model: an absorbed power law and a thermal component with \( kT \approx 1 \text{ keV} \) (Paizis et al. 2005), with the thermal component being interpreted as emission originating on a hot spot on the neutron star surface. Whereas the power-law photon index showed no evolution...
of broad emission lines of He first spectrum of the optical counterpart indicated the presence of X-ray variability during quiescence (Jonker et al. 2005).

The analysis of the X-ray spectrum showed clear evidence of X-ray variability during quiescence on three occasions with PCA data also revealed that J00291 showed atypical behavior compared to other neutron star low-mass X-ray binaries during outburst: the power spectra showed broadband flat-top noise with very low break frequencies (0.01–0.1 Hz) as well as the highest integrated fractional rms variability (≈50%) found to date in neutron star systems. These properties are more similar to those detected in low-hard states of black hole systems than neutron star systems (Lináres et al. 2007). J00291 was observed during quiescence on three occasions with Chandra. The first observation was taken a month after its discovery; the second and third observations were taken 12 and 36 days after the initial observation. The organization of the paper is as follows. We begin by describing in detail the data acquisition and reduction steps (§ 2). The whole outburst light curve from the monitoring campaign together with photometric observations during quiescence is presented in § 3. In § 4 we obtain constraints on the photometric variability of J00291 during outburst and quiescence, and in § 5 we derive a refined astrometric position for the source. The optical spectrum in outburst is analyzed in § 6. In § 7 we constrain the reddening toward J00291, and in § 8 we obtain the optical to near-infrared spectral energy distribution during outburst. Section 9 presents a detailed analysis of a new Chandra observation of J00291 in quiescence. The results are discussed in § 10, where we examine key questions such as the orbital parameters and distance toward J00291. Our conclusions are summarized in § 11.

### 2. OBSERVATIONS AND DATA REDUCTION

#### 2.1. Optical Photometry

Optical photometry of J00291 was obtained with the following telescopes (see also Table 1):

1. The 1.2 m telescope at the Fred Lawrence Whipple Observatory (FLWO) in Arizona. The Minicam mosaic camera was in place and J00291 was imaged with the FLWO Harris R-band filter, which closely approximates the Johnson-Cousins R broadband filter.
2. The 0.82 m IAC80 telescope at the Observatorio del Roque de los Muchachos on La Palma using the Aux Port imager, which carries a 1024 × 1024 pixel CCD camera.
3. The 4.2 m William Herschel Telescope (WHT) at the Observatorio del Roque de los Muchachos on La Palma using the Aux Port imager, which carries a 1024 × 1024 TEK CCD. The source was observed with the Harris R- and I-band filters with filter transmissions similar to that of Cousins filters.

4. The 2.5 m Isaac Newton Telescope (INT) at La Palma
using the Wide Field Camera (WFC), the four thinned EEV 2k × 4k CCDs and the Harris R-band filter.
5. The 3.5 m Telescopio Nazionale Galileo (TNG) at La Palma.
Cousins R- and I-band filters were used to acquire images with the DoLoReS instrument equipped with a 2048 × 2048 Loral CCD.
6. The MMT 6.5 m telescope at Mount Hopkins.
Data were obtained with the Sloan r′ filter and the MegaCam CCD mosaic camera (McLeod et al. 2000).
7. The 4.2 m WHT using the Prime Focus Imaging Camera (PFIP), which carries two 2148 × 4128 EEV CCDs.
Time-resolved photometry of J00291 in quiescence was acquired in the (Harris) R band.

Integration times ranged from 100 s to 10 minutes depending on telescope size, atmospheric conditions, and target brightness (see Table 1). The images were corrected for bias and flat-fielded in the standard way using IRAF.
We performed PSF-fitting photometry (Stetson 1987) on J00291 and several nearby comparison stars. We also performed a photometric calibration of a set of stars in the field of view of J00291 using several standard stars from Landolt plates (Landolt 1992) that were observed with the WHT, the 2.0 m Liverpool telescope on La Palma, and the FLWO 1.2 m telescope. The magnitudes for J00291 were obtained with differential photometry relative to these local comparison stars.

2.2. Optical Spectroscopy

Ten red and 10 blue spectra were acquired on the night of 2004 December 5 using the ISIS double-arm spectrograph attached to the WHT. J00291 was observed using a 1.5′ wide entrance slit with the CCDs on each spectrograph arm binned by two in the spatial direction. The blue arm was used with the R600B grating and the 4096 × 2048 EEV12 CCD array to yield an useful wavelength coverage of λ3500–5200 with a dispersion of 0.86 Å pixel⁻¹. The red arm was used with the R600R grating and the 2047 × 4611 MARCONI2 CCD. The useful wavelength range covered the λ5400–7100 interval with a dispersion of 0.88 Å pixel⁻¹. The spectral resolution was about ≳5.5 pixels FWHM for both arms.

The raw CCD frames were bias- and flat-field-corrected with standard IRAF routines. The spectra were extracted from each frame with the IRAF KPNOSLIT package. The pixel-to-wavelength calibration was derived from a cubic spline fit (blue spectrum) and a fifth-order Legendre polynomial fit (red spectrum) to copper-argon and copper-neon arc lamp spectra taken at each CCD. The rms deviation of the fit was < 0.1 and < 0.06 Å for the data acquired with the blue and red arms, respectively. No absolute flux calibration was attempted as the weather conditions were poor. The individual spectra were rebinned into a uniform velocity scale of 60.23 km s⁻¹ pixel⁻¹ (blue) and 41.92 km s⁻¹ pixel⁻¹ (red) to be rectified subsequently by fitting a spline function to the continuum after masking the emission lines.

2.3. Near-Infrared photometry

Infrared photometry during the X-ray outburst was obtained from 2004 December 8–11 with the 1.3 m Peters Automated Infrared Imaging Telescope (PAIRITEL) at FLWO (Bloom et al. 2006). The camera on PAIRITEL consists of three 256 × 256 NICMOS3 arrays that image simultaneously a 8.5′ × 8.5′ field of view in the J, H, and Ks photometric bands. The observations consisted of a large number of dithered 7.8 s exposures on source. The dithered exposures were first bias and flat-field-corrected to be mosaiced together for each individual visit (see, e.g., Blake et al. 2005). Total integration times per visit ranged between 3 and 15 minutes. For each visit, instrumental magnitudes were extracted and consequently calibrated relative to the same nearby 2MASS sources for all exposures. Photometric error estimates on the infrared magnitudes are based on a combination of Poisson statistics and the error contribution of the comparison stars used for each observation.

J00291 was also observed on two nights with the 3.8 m United Kingdom Infrared Telescope (UKIRT) on Mauna Kea. On December 28 the telescope was equipped with the UKIRT 1–5 μm Imager Spectrometer (UIST; Ramsay Howat et al. 2004). J-, H-, and K-band images were obtained on the 1024 × 1024 InSb array. Observations consisting of a single nine-point jitter pattern with a 30 s exposure at each offset position were performed using the K98 and J98 broadband filters, giving a total of 4.5 minutes on source. The same pattern was used with exposures of 60 s when using the J98 broadband filter, yielding 9 minutes on source. The J98, H98, and K98 filters are the Mauna Kea Observatory NIR Photometric System filters (see Simons & Tokunaga [2002] and Tokunaga et al. [2002] for more details). K-band observations were made on 2005 January 24 using the UKIRT Fast-Track Imager (UFTI; Roche et al. 2003) equipped with a 1024 × 1024 HgCdTe array. The observations were obtained by jittering the image on nine different positions. Exposures were 30 s at each position and the jitter pattern was repeated six times, yielding 27 minutes of total on-source observing time. The standard star FS103 from the set of UKIRT faint standards was observed for photometric calibration. During both nights a dark frame was obtained in each filter at the start of each set of observations. The data were reduced through the automated ORAC-DR pipeline (Allan et al. 2002): the individual frames from each filter were bad-pixel-masked, dark-subtracted, flat-fielded (a flat field was made using the target frames), and combined to form mosaics. Absolute calibration of the K-band mosaic obtained with UFTI was performed with the standard star using a median extinction value of 0.088 mag air mass⁻¹ at the Mauna Kea summit. The resulting absolute magnitudes for the 2MASS stars in the field differed by ≳0.05 ± 0.03 mag. The small discrepancy is consistent with the expected 2% differences between magnitudes obtained by calibrating with 2MASS and UFTI standard stars (Hodking et al. 2006; Nikolaev et al. 2000). J00291 was not detected in any of the UFTI mosaic frames. These frames were calibrated using 2MASS stars in the field and 3 σ upper limits to the near-infrared magnitudes of the source were derived from aperture photometry made to the field stars.

Details of all the observations are summarized in Table 1.

2.4. X-Ray Data: Observations and Reduction

We observed J00291 with the backside-illuminated ACIS-S3 CCD on board the Chandra satellite. The observation (ObsID 6570) started on 2005 November 24 09:49:44 UT. The total on-source time was 24671.5 s. We limited the readout area of the S3 chip to one-eighth of its original size yielding a smaller exposure time per CCD frame in order to avoid pile-up. The data were reprocessed in a standard way using the CIAO 3.3.0 software. We searched the data for periods of enhanced background radiation, but none were found. Hence, all the data were used in our
analysis. Following Jonker et al. (2005), we extracted the spectrum of J00291 from a circular region with a 3 pixel radius centered on the best-fit source position as provided by wavdetect, whereas the background spectrum was extracted using an annulus centered on the source position with inner and outer radius of 10 and 30 pixels, respectively. We detect a total of 143 counts in the source region and 296 in the background region. This of 10 and 30 pixels, respectively. We detect a total of 143 counts whereas the background spectrum was extracted using an annulus centered on the best-fit source position as provided by wavdetect. Open triangles mark R-band magnitudes reported by Fox & Kulkarni (2004) and Bikmaev et al. (2005). The latter were taken by digitizing the published light curve. Arrows denote upper limits. The dotted curve shows the first exponential fit described in § 3. For the sake of comparison this curve is plotted from 2004 December 2 09:00:19 UTC (source discovery with INTEGRAL) to 2004 December 22 00:00. Times of the WHT spectroscopy during outburst and Chandra X-Ray Observatory (CXO) observations during quiescence (Jonker et al. 2005) are marked as WHT, CXO1, and CXO2, respectively. The third Chandra observation, on MJD 53407.57, is not shown.

3. THE OUTBURST LIGHT CURVE

Figure 1 presents the overall optical/infrared light curve. Each data point represents the mean magnitude per night at each respective bandpass. The discovery optical magnitude (R \( \approx \) 17.4; Fox & Kulkarni 2004) and the R-band photometry reported in Bikmaev et al. (2005) have also been included. Note that the follow-up of J00291 could not be continuous as it was hampered by poor weather conditions during the winter season in the Northern Hemisphere.

Our first images were taken on 2004 December 8, and showed the source at R = 18.33 \pm 0.07 mag, I = 17.58 \pm 0.06 mag, J = 17.1 \pm 0.1, H = 16.7 \pm 0.2, and K = 15.9 \pm 0.1. We fitted an exponential to our first eight R-band data points, which describes well the decline in brightness (the rms from the fit was 0.11 mag). From the fit we infer a rate of decline of 5.2 \pm 0.4 days mag\(^{-1}\) and thereby an \( e \)-folding time of 5.7 \pm 0.4 days in flux. Assuming the transient started to decay with the same trend after the outburst peak, the extrapolation of the exponential fit to the time of the discovery by INTEGRAL (Eckert et al. 2004, Shaw et al. 2005) yields a peak optical brightness of \( R = 17.03 \pm 0.08 \text{ mag} \). Our JHK\(_s\)-band coverage is not sufficient to determine the flux decay rate at near-infrared wavelengths.

In Figure 2 we plot the R-band magnitudes during the initial decay together with the RXTE PCA outburst light curve. A first account of the PCA light curve is given by Galloway et al. (2005) and Paizis et al. (2005). We digitized their data and plotted them on a logarithmic scale in Figure 2. This figure shows that the X-ray light curve decays exponentially with an initial \( e \)-folding time of 8.5 \pm 0.3 days. An exponential decay is expected to happen in short-orbital period binaries such as J00291 because the X-ray irradiation is strong enough to ionize the entire accretion disk (King & Ritter 1998; see also discussion). The decay becomes faster after 2004 December 10.2, when the \( e \)-folding time becomes 2.6 \pm 0.1 days. INTEGRAL ISGRI observations (10–100 keV) also show a change in the rate of decline in the light curve close to 2004 December 10, when the initial 6.6 day \( e \)-folding time decreases to 2.2 days (Falanga et al. 2005). The optical light curve does not show such a change until 2004 December 15, when there is indication of a steeper decline in the optical brightness. The optical data are consistent with a decay with rate 2.2 \pm 0.5 days mag\(^{-1}\) (\( e \)-folding time of 2.4 \pm 0.5 days).

On 2004 December 19, J00291 was found to be at \( R = 20.90 \pm 0.06 \text{ mag} \), and it is difficult to assess the light curve morphology due to the lack of coverage after that date. It is possible that the brightness decline slowed down or/and the source underwent minioutbursts/reflares in the optical before it reached quiescence. In this regard, the magnitudes reported by Bikmaev et al. (2005; Fig. 1, open triangles) together with our data seem to be consistent with what could have been an optical minioutburst with amplitude \( \approx 0.4 \text{ mag} \) starting about 2005 January 7 and lasting for about a week. At that time J00291 had definitely ceased its X-ray activity and settled down into quiescence at X-ray wavelengths (Jonker et al. 2005). The unreddened \( R - I \) color during the outburst decline was 0.75 \pm 0.09 mag (2004 December 8), 1.1 \pm 0.2 mag (2004 December 30), and 0.7 \pm 0.3 mag (2005 December 15).
January 7). We cannot draw any conclusion about the evolution of the color index given the large error bars, which were calculated by adding quadratically the uncertainties on the R- and I-band photometry.

By the end of the possible optical minioutburst and our outburst follow-up (2005 January 14), the optical magnitude had declined to $r' = 22.7 \pm 0.1$. Ten days later, J00291 was imaged with UKIRT to derive a $K = 19.0 \pm 0.1$ mag for its near-infrared counterpart in quiescence. Finally, we observed J00291 with the WHT on 2005 October 25 and 26 to measure a mean magnitude of $R = 23.1 \pm 0.1$ for the optical counterpart in quiescence. This yields a total amplitude for the optical outburst of $\Delta R > 4.8$ mag ($\Delta R = 6.1$ mag from the above extrapolation) and $\Delta K > 3.1$ mag.

4. PHOTOMETRIC VARIABILITY

Time-resolved photometry of J00291 over the course of the outburst decline suggested significant variability on timescales of tenths of minutes to hours with amplitude $\leq 0.3$ mag (Bikmaev et al. 2005; Reynolds et al. 2006), but gave no indication of the orbital period. Our photometric data sets were also searched for short-term photometric variability when more than four data points per night were available. Quantifying the variability of J00291 requires care, since some of our data were acquired under variable weather conditions. We have dealt with this by carrying out photometry of field stars with similar brightness to J00291 or fainter in order to determine the significance of our photometry through the standard deviation on their magnitudes.

Seven images in the JHK bands were made with PAIRITEL on 2004 December 10. The rms of the J00291 mag is 0.12–0.15 mag, not different from the comparison stars in the field of view. Any rms flux variations of J00291 over the observing interval cannot be much greater than $\approx 15\%$.

We obtained seven R-band images during 2004 December 30 with the WHT and six R-band images during 2005 January 7 with the TNG. We constrain the rms flux variation in J00291 to be $\leq 7\%$ and $\leq 16\%$ during the small fraction of the orbit covered during the observations (0.15 and 0.087 orbital cycles for the WHT and TNG, respectively).

Time-resolved photometry of J00291 in quiescence was acquired on 2005 October 25 with the WHT. We obtained five 300 s and twenty 600 s R-band frames. The rms deviation in the photometry over the 1.41 orbital cycles covered by the 600 s images (the data with higher S/N ratio) is 0.25 mag, 2 times larger than the rms observed for two fainter comparison stars. The intrinsic rms flux variability of J00291 in the R-band light curve is constrained to be $\approx 22\%$ by subtracting in quadrature the rms flux variation of the comparison stars from the variability observed in J00291. To examine the variability we used both PSF and optimal aperture techniques to determine the magnitudes that gave similar values. We do not see any evidence for orbital modulation in the photometric variability.

5. ASTROMETRY

The position of J00291 was determined using the higher resolution images acquired at different epochs during the outburst decline. These were the images obtained with UKIRT/UTFI (pixel scale of 0.091 arcsec pixel$^{-1}$), WHT/Aux Port (0.237 arcsec pixel$^{-1}$), TNG/DoLoReS (0.551 arcsec pixel$^{-1}$) and MMT/MegaCam (0.160 arcsec pixel$^{-1}$). The transformation from pixel to sky coordinates was computed using the IRAF tasks center and cctran on 6–12 bright stars whose PSFs were not corrupted by CCD oversaturation effects. The positions for these internal astrometric reference stars were taken from 2MASS and they have an accuracy of $0.1'' - 0.2''$ (Skrutskie et al. 2006). The rms errors of the astrometric fit were 0.05'' and 0.01'' (UKIRT), 0.02'' and 0.07'' (WHT), 0.05'', and 0.06'' (TNG), and 0.06'' and 0.07'' (MMT) for right ascension and declination, respectively. The error on the position of J00291 provided by the centroid task was always $< 0.03''$. Using the mean of the four measurements we determined a refined position for J00291 of $\alpha = 00^h 29^m 03.05^s \pm 0.01''$ and $\delta = +59^\circ 34' 18.93'' \pm 0.05''$ (J2000.0). The errors represent the rms of the measurements. The above value is in good agreement with the positions reported for the optical and X-ray counterparts (Fox & Kulkarni 2004; Paizis et al. 2005). It differs from the position for the radio counterpart (Rupen et al. 2004) by 3.2 $\sigma$ in right ascension, corresponding to an angular offset between both positions of 0.25''.

6. THE AVERAGED SPECTRUM

As indicated in Figure 1, our spectroscopic observations took place on 2004 December 5 during the initial decline of the outburst when the optical brightness was $R = 17.72 \pm 0.05$ according to our exponential fit to the optical light curve (§3). The data cover 4.5 contiguous hours of spectroscopy representing 1.8 orbital cycles. The individual spectra have a signal-to-noise ratio (S/N) $\approx 10$ at 4500 Å and S/N $\approx 10$ at 6300 Å. We produced an average spectrum by assigning optimal weights to the individual spectra to maximize the S/N of the sum. Figure 3 presents the weighted sum. The spectra show the presence of broad Balmer lines up to likely H6 in emission. The line profile for H$\alpha$ is double-peaked. An F-test gives a probability $> 99.99\%$ confidence that a double-Gaussian fit is better representation of the H$\alpha$ profile than a single Gaussian fit. Due to the low S/N it is difficult to assess whether or not the H$\beta$ and H$\delta$ profiles are double-peaked as well. The high-excitation He $\lambda\lambda 4686$ emission line is present, but we do not detect the Bowen blend (at $\lambda\lambda 4640$). In Table 2 we list the measured line profile parameters: the velocity shift of each line respect to the rest wavelength, the centroid of the line and the peak-to-peak separation (for H$\alpha$ only), the FWHM, the full-width zero intensity (FWZI), and the equivalent width (EW). The values reported are the mean of the measurements obtained by selecting different wavelength intervals to set the underlying continuum and the uncertainties correspond to the standard deviation. Table 2 shows that the emission line profiles are blueshifted respect to their rest wavelength. This shift more likely reflects the systemic radial velocity (neutron star systems tend to have high systemic velocities; see, e.g., White & van Paradijs 1996) and/or the presence of a precessing accretion disk (as observed in short-orbital period X-ray transients in outburst; see, e.g., Torres et al. 2002, 2004 and references therein). H$\alpha$ is the dominant emission line in the spectrum with a FWHM of 1340 $\pm$ 10 km s$^{-1}$ and $\text{FWZI} = 6.5 \pm 0.4$ Å. The velocity separation of the peaks in the averaged profile is 650 $\pm$ 40 km s$^{-1}$. He $\lambda 5875$ in emission seems to be detected. In this regard, He $\lambda 6667$ was reported from a single 300 s spectrum obtained on 2004 December 12 (Filippenko et al. 2004) when the source brightness was $R = 18.93 \pm 0.08$. A visible inspection of this spectrum (see Fig. 1 in Reynolds et al. 2006) shows that He $\lambda \lambda 5875, 7065$ emission lines were also present. We measured the EW and radial velocity of the individual H$\alpha$ and He $\lambda 4686$ emission line profiles. Neither the EW nor the radial velocities showed significant modulation with the orbital motion.

The main interstellar features detected are the partially resolved atomic Na D doublet at $\lambda \lambda 5889.95, 5895.92$ (total EW of 1.1 $\pm$ 0.1 Å) and the Ca $\lambda \lambda 3933.67, 3968.47$ lines (EWs of 0.45 $\pm$ 0.02 and 0.38 $\pm$ 0.04 Å, respectively). The spectra show
also the presence of diffuse interstellar bands at $\lambda 5780$ (EW = 0.4 ± 0.1 Å), $\lambda 6203$ (EW = 0.22 ± 0.02 Å) and $\lambda 6284$ (EW = 1.9 ± 0.4 Å). The broad 6284 Å band profile is contaminated with telluric O$_2$. Longward of $\approx$6800 Å, the spectra are also contaminated by telluric features.

7. REDDENING TOWARD J00291

Knowledge of the interstellar extinction is necessary in order to determine the distance to the source and its spectral energy distribution. $E(B - V)$ can be estimated in a number of different ways. From its location in the Galaxy ($l = 120.1^\circ$, $b = -3.2^\circ$), the expected color excess is $\leq 0.05$ mag according to the average H$_2$ column ($N_{\text{H}_2}$) obtained by weighting the $N_{\text{H}_2}$ values within 1° along the line of sight to the source with the inverse of the distance from the source position ($N_{\text{H}_2} \approx 4.66 \times 10^{21}$ cm$^{-2}$; Dickey & Lockman 1990). Here we adopt $N_{\text{H}_2}/E(B - V) = 5.8 \times 10^2$ cm$^{-2}$ (Bohlin et al. 1978). $E(B - V) \leq 0.71$ mag using the all-sky reddening maps based on far-infrared emission at 100 and 240 $\mu$m from dust (Schlegel et al. 1998). Note that both radio and dust maps integrate along the whole line of sight through the Galaxy and that the reddening maps are expected to have reduced accuracy for $|b| < 6^\circ$. Fits to the X-ray spectra acquired with Chandra and RXTE during the X-ray outburst (Paizis et al. 2005) provided $N_{\text{H}_2} = (4.3 \pm 0.4) \times 10^{21}$ cm$^{-2}$ (High Energy Transmission Grating Spectrometer spectrum [HETGS]) and $N_{\text{H}_2} = 4.3^{+0.5}_{-0.3} \times 10^{21}$ cm$^{-2}$ (combined Chandra HETGS and RXTE PCA spectrum). These values imply a range of $E(B - V) = 0.66 - 0.86$ mag in extinction. Finally, a reddening of $E(B - V) = 0.8 \pm 0.2$ mag can be derived from the calibration between reddening and the EW for the $\lambda 5780$ diffuse interstellar band (Herbig 1993). Note that we use only this interstellar band as it shows a better correlation with reddening than the other diffuse interstellar bands in our spectrum (see Herbig 1975). Based on the above four independent results, we adopt $0.7 \leq E(B - V) \leq 0.9$ ($=4.06 \times 10^{21}$ cm$^{-2}$) as a likely range of the extinction by giving a lower weight to the result from the $\lambda 5780$ DIB, which is the least precise method for deriving the reddening given the uncertainties in the $E(B - V)/$EW relationship and the errors in the EW measured for this DIB. The lower limit on $E(B - V)$ yields a dereddened color of $(R - I)_0 = 0.45 (R - I = 0.75; \S 3)$, indicating a temperature of the order of 5000 K when assuming a thermal origin for the optical flux. This temperature

### Table 2: Emission-Line Parameters from the Average Spectrum

| Emission Lines | $\gamma$ (km s$^{-1}$) | $(V_b + V_r)/2$ (km s$^{-1}$) | $V_r - V_b$ (km s$^{-1}$) | FWHM (Å) | FWZI (Å) | EW (Å) |
|----------------|------------------------|-------------------------------|--------------------------|----------|---------|--------|
| H$_\alpha$      | $-122 \pm 9$           | $-53 \pm 18$                 | $650 \pm 40$             | $30.4 \pm 0.3$ | $52 \pm 3$ | $6.5 \pm 0.4$ |
| H$\beta$       | $-156 \pm 18$          | ...                           | ...                      | $22 \pm 1$ | $35 \pm 3$ | $2.4 \pm 0.3$ |
| H$\gamma$      | $-67 \pm 13^*$         | ...                           | ...                      | $26 \pm 1$ | $33 \pm 3$ | $2.9 \pm 0.2$ |
| He $\alpha$ $\lambda$ 6678 | $-53 \pm 35$          | ...                           | ...                      | $24 \pm 2$ | $36 \pm 3$ | $1.7 \pm 0.3$ |
| H$\delta$      | $-142 \pm 22$          | ...                           | ...                      | $24 \pm 1$ | $31 \pm 3$ | $1.2 \pm 0.4$ |

*Notes.—* By $\gamma$ we designate the positions (shifts) respect to the rest wavelength of the line and was measured with a Gaussian fit as the FWHM; $V_b$ and $V_r$ designate the shifts respect to the rest wavelength of the line of the blue and red peaks, respectively and were measured using the task *aplot* in IRAF.

* After masking the emission spike on top of the line profile.
In X-ray transients in outburst the continuum emission will fall gradually from optical to infrared wavelengths when the thermal spectrum of the X-ray and/or viscously heated accretion disk dominates the flux output at these wavelengths (see, e.g., Beall et al. 1984; Vrtilek et al. 1990; Hynes 2005, Russell et al. 2006). Our SEDs show a break in the expected trend at infrared wavelengths where there is significant excess flux in the K band during the four nights and likely in the H band on December 11 as well. This supports the presence of another source of near-infrared flux in the spectrum. This source cannot be emission from the donor star as its contribution to the near-infrared flux is <8% during outburst. This estimation is based on the K-band magnitudes measured during outburst and in quiescence (§3). The near-infrared excess can be explained by invoking optically thin synchrotron emission, which is expected to contribute to the SED with a component with spectral index \( \alpha < 0 \) (see Fender 2006 and references therein). This nonthermal component has been claimed to explain the excess of optical/near-infrared flux observed during the outburst of the accreting millisecond X-ray pulsars SAX J1808.4–3658 (\( P_{\text{orb}} = 2 \) hr; Wang et al. 2001; Greenhill et al. 2006), XTE J0929–314 (\( P_{\text{orb}} = 43.6 \) minutes; Giles et al. 2005) and XTE J1814–338 (\( P_{\text{orb}} = 4.3 \) hr; Krauss et al. 2005). The detection of mid-infrared optically thin synchrotron emission from a jet in the neutron star 4U 0614+091 (Migliari et al. 2006) adds support to the above claim. For illustration purposes, we show in Figure 4 a power-law fit (\( F_\nu \propto \nu^\alpha \)) to the 2004 December 8 data performed after excluding the flux at the K band. It is clear that the fit is a poor description of the data: \( \chi^2 \) is 2.4 and furthermore we cannot exclude the very likely presence of flux excess at H and J bands and shorter (optical) wavelengths due to the nonthermal (jet) component that will make the SED flatter (redder). The near-infrared unabsorbed flux measured on December 9 (0.30 ± 0.01 mJy at 2.159 \( \mu \)m, 0.33 ± 0.02 mJy at 1.662 \( \mu \)m, and 0.43 ± 0.02 mJy at 1.235 \( \mu \)m) lies above the radio flux of 0.17 ± 0.07 mJy at a frequency of 4.86 GHz measured that day by Rupen et al. (2004; see also Fender et al. 2004). This suggests a spectrum with spectral index (\( \alpha \geq 0 \)) implying a flat or slightly inverted synchrotron optically thick spectrum.

9. X-RAY DATA: ANALYSIS

A month after J00291 went into outburst a 4.7 ks Chandra ACIS-S observation detected the source at an unabsorbed flux of \((7.9 \pm 2.5) \times 10^{-14} \) ergs cm\(^{-2}\) s\(^{-1}\) (0.5–10 keV). A serendipitous 18 ks observation by ROSAT obtained over 1992 July 26–August 4 also showed J00291 at a similar flux level, confirming its return to quiescence within a month. Additional 9 and 12.9 ks Chandra observations obtained on 2005 January 13 and 2005 February 6 showed the source at an unabsorbed flux of \((7.3 \pm 2.0) \times 10^{-14}\) and \((1.17 \pm 0.22) \times 10^{-13} \) ergs cm\(^{-2}\) s\(^{-1}\), revealing that J00291 is variable in quiescence (see Jonker et al. 2005 for more details).

In this section we analyze an additional 24.6 ks Chandra observation acquired on 2005 November 24. We performed a similar spectral analysis to that presented in Jonker et al. (2005) using XSPEC (ver. 11.3; Arnaud 1996). We rebinned the source spectrum such that each bin contains at least 10 counts and used data in the energy range 0.5–10 keV. Due to the low number of source counts per bin, we also checked the spectral fitting results using the Cash statistic (Cash 1979), the results were consistent with those found using \( \chi^2 \) fitting. For all spectral fits the hydrogen column density toward J00291 was held fixed at \( N_\text{H} = 4.6 \times 10^{21} \) cm\(^{-2}\), a likely value of the hydrogen column density as
derived in this paper (§ 7). Note also that the X-ray light curve shows no significant variability. A Kolmogorov-Smirnov test gives a probability of 25% for the count rate of the source to be constant.

We began by fitting the spectrum using single component models: a power-law model, a neutron star atmosphere (NSA) model, and a black-body model. For the NSA model we fixed the neutron star magnetic field, its radius and mass at 0 G, 10 km, and 1.4 $M_\odot$, respectively. The temperature and normalization were the only allowed free parameters. The results of these fits are shown in Table 3. As can be seen in Table 3, the single-thermal models did not provide an adequate fit to the data ($\chi^2 > 3.2$) and yield a temperature for J00291 considerably higher than the temperature observed for other neutron star X-ray transients in quiescence. We reject these models on this basis. A single-power-law model was statistically acceptable with $\chi^2_{\text{red}} = 1.2$ for 11 degrees of freedom (dof). In Figure 5 we have plotted the spectrum showing the power-law fit. The absorbed 0.5–10 keV source flux from the best-fitting power-law model is $(3.8 \pm 1.0) \times 10^{-14}$ ergs cm$^{-2}$ s$^{-1}$ whereas the unabsorbed flux is $(7.0 \pm 0.9) \times 10^{-14}$ ergs cm$^{-2}$ s$^{-1}$. We also list in Table 3 the unabsorbed 0.5–10 keV flux derived from other models fit to the data. Note here that the X-ray spectrum of the transient millisecond X-ray pulsars SAX J1808.4–3658 (Campana et al. 2002, 2005) and XTE J0929–314 (Wijnands et al. 2005) are also consistent with an absorbed power-law spectrum. The source flux from the best-fitting power-law model is consistent with the values found using previous Chandra and ROSAT observations of J00291 during quiescence (Jonker et al. 2005).\footnote{Note that Jonker et al. (2005) used $N_H = 2.8 \times 10^{21}$ cm$^{-2}$ in their work. This value of $N_H$ was derived from preliminary analysis of a 18 ks Chandra observation acquired at the end of the X-ray outburst (Nowak et al. 2004), and it has been extensively used in the literature. In the present work, the power-law index and temperature model parameters obtained using $N_H = 2.8 \times 10^{21}$ cm$^{-2}$ are consistent within the errors with those obtained using $N_H = 4.6 \times 10^{21}$ cm$^{-2}$, whereas the unabsorbed flux is smaller. For comparison, the absorbed, and unabsorbed fluxes are $(4.3 \pm 0.9) \times 10^{-14}$ and $(6.0 \pm 0.6) \times 10^{-14}$ ergs cm$^{-2}$ when $N_H$ was frozen to $2.8 \times 10^{21}$ cm$^{-2}$ during the fit.}

### Table 3

| Model       | Temperature/PL Index | Unabsorbed 0.5–10 keV Fluxes (10$^{-14}$ ergs cm$^{-2}$ s$^{-1}$) | $\chi^2_{\text{red}}$ (dof) | NHP (%) |
|-------------|----------------------|-----------------------------------------------------------------|-----------------------------|---------|
| BB          | 0.6 ± 0.2$^a$        | 3.8                                                             | 3.4 (11)                    | 0.01    |
| NSA         | 6.5$^{+0.4}_{-0.3}$  | 3.9                                                             | 3.2 (11)                    | 0.02    |
| PL          | 2.4$^{+0.3}_{-0.1}$  | 7.0                                                             | 1.2 (11)                    | 28      |

Notes.—NSA, BB, and PL stand for the neutron star atmosphere, blackbody, and power-law models. Quoted uncertainties for the parameters of interest in these single-component models are given at the 90% confidence level ($\Delta \chi^2 = 2.71$). NHP = null hypothesis probability.

$^a$ Unit: keV.

$^b$ Unit: log K.

Figure 2 shows that the X-ray light curve decays exponentially with a break or “knee” where the e-folding time becomes faster. A similar break has clearly been observed in the decay X-ray light curves of three other millisecond pulsars: SAX J1808.4–3658 ($P_{\text{orb}} = 2$ hr; Wijnands & van der Klis 1998; Gilfanov et al. 1998; Wijnands 2005 and references therein), XTE J1751–305 ($P_{\text{orb}} = 42$ minutes; Markwardt et al. 2002; Gierlinski & Poutanen 2005) and XTE J0929–314 ($P_{\text{orb}} = 43.6$ minutes; Giles et al. 2005; Powell et al. 2007). In the three systems the break was from an exponential decay to a linear decay (see Powell et al. 2007). A break from a slow to a fast exponential decay has been observed in the light curves of the neutron star X-ray transients Aquila X-1 ($P_{\text{orb}} = 18.95$ hr; Maitra & Bailyn 2004) and Centaurus X-4 ($P_{\text{orb}} = 15.1$ hr; Evans et al. 1970; Kaluzienski et al. 1980; Chen et al. 1997, Shahbaz et al. 1998). The initial exponential decay in the light curves of X-ray transients has been explained by assuming that the evolution of the mass in an irradiated disk is described as $M_{\text{disk}} = -M_\text{c} \propto M_{\text{disk}}$, where $M_\text{c}$ is the central mass accretion rate. Thus $L_X \propto M_\text{c} = M_{\text{disk}}^0 e^{-\alpha \tau}$ where $M_{\text{disk}}^0$ is the initial mass of the irradiated...
disk. A faster decay phase (steeper light curve) is expected to occur when the central accretion rate (and thus the X-ray flux) has decreased below the critical X-ray luminosity necessary to keep the outer parts of the disk ionized. Then a cooling front (previously inhibited by X-ray irradiation) will move inward the disk and switch off the outburst. The rate of decay in the light curve during the propagation of the cooling front has been observed to be either linear or exponential, sometimes showing departures due to one or more secondary maxima that appear during the outburst decline. Details on models for the understanding of the outburst light curves and the outbursts themselves can be found in King & Ritter (1998), Dubus et al. (2001), Lasota (2001), and Powell et al. (2007).

The ratio of the optical exponential decay time to the X-ray exponential decay time \[ \frac{\tau_{\text{opt}}(V)}{\tau_{\text{opt}}(X)} \] is expected to be \( \approx 2 \) for X-ray transients when the optical flux is dominated by X-ray reprocessing on the disk (King & Ritter 1998). Observational evidence supporting this prediction is that \( \frac{\tau_{\text{opt}}(V)}{\tau_{\text{opt}}(X)} \approx 1.9 \) in X-ray novae (Chen et al. 1997). This ratio is \( \tau_{\text{opt}}(V)/\tau_{\text{opt}}(X) = 0.67 \pm 0.05 \) before the knee in the X-ray light curve of J00291. Apart from J00291, SAX J1808.4–3658 is the only millisecond pulsar for which well-sampled optical and X-ray light curves are available (1998 outburst). For this system we derive \( \tau_{\text{opt}}(V)/\tau_{\text{opt}}(X) = 1.5 \). The fact that the decay in the optical light curve of J00291 is faster than observed in X-ray irradiated systems suggests that X-ray heating is insufficient to be the dominant source of optical emission and that viscous dissipation in the disk may make a significant contribution to the optical flux. For instance, the optical light curves of dwarf novae in outburst follow the soft X-rays after the outburst peak \( \frac{\tau_{\text{opt}}(V)}{\tau_{\text{opt}}(X)} \approx 1 \) to decline slower than the X-rays a few days later (J ones & Watson 1992; Mauche et al. 2001; Wheatley et al. 2003).

The knee in the optical light curve of J00291 is delayed \( \approx 4.7 \) days with respect to the knee in the X-ray light curve (Fig. 2). A delay of \( \approx 7 \) days was observed in SAX J1808.4–3658 (Wang et al. 2001). After the knee, the optical and X-ray light curves of J00291 decay faster with a similar \( e \)-folding time, \( \frac{\tau_{\text{opt}}(V)}{\tau_{\text{opt}}(X)} = 0.8 \pm 0.2 \). This was not the case during the 1998 outburst of SAX J1808.4–3658, when the flux at optical wavelengths reached a plateau that lasted 1 month (Wang et al. 2001). The optical decay in J00291 \( (2.2 \pm 0.5 \text{ days mag}^{-1}; \; \text{opt}) \) is slower than the 0.93 \( \pm 0.05 \text{ days mag}^{-1} \) rate predicted by the relationship for dwarf novae (nonmagnetic cataclysmic variables [CVs]) between the rate of the decay and the orbital period (Bailey 1975). This is observed by Smak (1999) as \( (dV/dr)^{-1} = (0.38 \pm 0.02) \text{P}_{\text{orb}} \text{(hr)} \). In order to use we have assumed \( dR/dr \approx dV/dr \) during the decline of J00291. It is interesting to note that a few intermediate polars (CVs where the accretion disk is disrupted by the magnetic field of the white dwarf as expected in millisecond pulsars) have shown dwarf-nova-like outbursts that decay faster than the Bailey’s relationship. Examples of these are DO Dra (P_{\text{orb}} = 3.96 hr; Simon 2000) and HT Cam (P_{\text{orb}} = 1.35 hr; Ishioka et al. 2002). In summary, J00291 seems to show during the late decline a longer decay time compared to dwarf novae as has been observed in other X-ray transients. For instance, the optical flux of the neutron star transient XTE J2123–058 (P_{\text{orb}} = 5.96 hr) decayed with a rate of 5.00 \( \pm 0.02 \text{ days mag}^{-1} \) in the \( V \) band and 11.8 \( \pm 0.3 \text{ days mag}^{-1} \) in the \( R \) band at the end of the 2000 outburst (Soria et al. 1999; see also Zurita et al. 2000).

10.2. The Nature of the Donor Star

The lack of eclipses or dips in the outburst X-ray light curve imply an inclination \( i \approx 85^\circ \). This limit combined with the mass function derived from X-ray data (2.81311 \( \times 10^{-5} \text{ M}_\odot \); Galloway et al. 2005) implies a donor star mass \( M_d \approx 0.04(0.05) \text{ M}_\odot \) for assumed neutron star mass \( M_1 = 1.4(2.0) \text{ M}_\odot \). Assuming that the inclination of J00291 is drawn from an isotropic distribution of inclination angles, using the mass function and applying the requirement that the companion fits within its Roche lobe lead to the expectation that the donor star is a \( \lesssim 0.16 \text{ M}_\odot \) confidence low-mass star, most likely a brown dwarf bloated by the pulsar X-ray emission (Galloway et al. 2005).

We can use the peak-to-peak separation in the H\(_\alpha\) emission profile \( (\Delta V_{25}/C_{28}) = 650 \pm 40 \text{ km s}^{-1} \) to estimate the inclination of the system by assuming that the peaks in the averaged profile represent emission from gas orbiting in the outer radius of the disk with a Keplerian motion. In such a case \( \Delta V_{25}/C_{28} = 2R_{\text{out}}/a_1 \) sin \( i \), where \( i \) is the Keplerian motion with respect to the tidal radius \( R_1 \) (at which the tidal forces of the donor star cut the disk off) and the radius of the 3:1 Lindblad resonance radius \( R_{3:1} \) (at which orbits in the disk resonate with the donor-star orbit, driving the disk elliptical). \( R_1 \approx 0.9R_1(1) \), where \( R_1(1) \) is the volume radius of the Roche lobe of the compact star and \( R_{3:1} \approx 3^{-2/3}(1 + q)^{1/3}\ln a_1/12\text{ M}_\odot/m_1 \) and \( a_1 \approx 2R_{\text{out}}/a_1 \) is the separation between both stellar components (see, e.g., Whitehurst & King 1991). The orbital parameters measured for J00291 allow us to estimate \( R_1(1) \) as a function of the mass for the stellar components and \( a_1 \) (Eggleton 1983). Using Kepler’s third law together with the constraints on the donor and neutron star mass we obtain \( 1.04 < a_1 < 1.19 \text{ M}_\odot \) and \( 0.56 \text{ M}_\odot < M_1 < 3.46 \times 10^{10} \text{ cm} \) at the outburst (Soria et al. 1999; see also Zurita et al. 2000). From \( \Delta V_{25}/C_{28} \) we estimate a system inclination of \( i \approx 22^\circ - 32^\circ \). This range of inclinations implies a donor star with mass \( M_d \approx 0.04 - 0.11 \text{ M}_\odot \) for a \( M_1 = 1.4(2.0) \text{ M}_\odot \) neutron star when using the mass function of the pulsar derived from X-ray data.

Similarly, an upper limit to the inner radius of the H\(_\alpha\)-emitting regions during outburst \( R_{\text{in}} \) can be obtained by assuming Keplerian motion for the gas. From the maximum velocity extent of the H\(_\alpha\) line profile \( (FWZI = 2400 \pm 100 \text{ km s}^{-1}) \) we derive \( R_{\text{in}} \approx 4GM_1/3(P_{\text{spin}}/4\pi)^{1/3} = 2.11 \times 10^{6}M_1^{1/3}(\text{M}_\odot) \text{ cm} \), where \( P_{\text{spin}} \) is the neutron star spin period.

From our photometry during quiescence we find \( (R - K) \approx 4.1 \pm 0.1 \text{ mag} \), which corrected from extinction corresponds to an unabsorbed \( (R - K)_0 \) color of 2.3 \( \pm 0.3 \) mag. We plot in Figure 6 the theoretical mass-\( (R - K) \) color tracks for low-mass stars with solar metallicity and ages of 0.1 to 10 Gyr (Baraffe et al. 1998). The gigayear tracks intersect the mass versus \( (R - K) \) diagram at \( 0.65 \text{ M}_\odot < M_1 < 0.78 \text{ M}_\odot \). For these masses the inclination derived using the mass function is \( i \approx 4.0 - 5.0^\circ \), which is highly unlikely given the FWHM and the double-peaked profiles of the emission lines, and the fact that the donor star will be much larger than its Roche lobe (Fig. 6). This discrepancy can be explained if the donor star and accretion disk are irradiated by a relativistic particle wind from the pulsar, which resums activity during quiescence (see, e.g., Campana et al. 2004) or by residual accretion onto the neutron star surface and by thermal X-ray emission from the pulsar surface, which

\begin{align*}
13 \text{ Here } \tau_{\text{opt}}(V) = 7.4 \text{ days and } \tau_{\text{opt}}(R) = 7.9 \text{ days. These values were obtained using the photometric data from Table 1 in Wang et al. (2001). Only data until MJD 50932.7 were used; } \tau_{\text{opt}}(1.5 - 12 \text{ keV}) = 4.89 \pm 0.06 \text{ days (Powell et al. 2007).}
\end{align*}
is heated during outbursts (see, e.g., Bildsten & Chakrabarty 2001).

10.3. The Distance toward J00291

Different methods have been used to constrain the distance. First, Galloway et al. (2005) estimated a lower limit of \( \approx 4 \) kpc by assuming that the 2004 outburst fluence is typical for the system and that the mass transfer rate is driven by gravitational radiation. These authors suggested that the distance cannot be much larger, based on the fact that thermonuclear bursts were not detected during the outburst event. Second, Jonker et al. (2005) derived a distance of \( 2.6 \pm 0.36 \) kpc by assuming that the quiescent X-ray luminosity of J00291 is similar to that measured for the millisecond pulsars SAX J1808.4–3658 and XTE J0929–314 in quiescence. Using SAX J1808.4–3658 alone (for which \( d \approx 3.4–3.6 \) kpc, Galloway & Cumming 2006) and the unabsorbed flux of J00291 during quiescence measured in § 8, we roughly estimate the distance toward J00291 to be \( 2.0–3.4 \) kpc.

The distance to J00291 can also be constrained using the critical X-ray luminosity necessary in a neutron star X-ray transient

---

**Fig. 6.** Left: Predicted color \((R - K)\) as a function of the mass for low-mass stars with ages 0.1, 0.5, 5, and 10 Gyr. Isochrones are taken from Baraffe et al. (1998). The dashed lines delinate our constraint on the \((R - K)\) quiescent color of J00291. Right: Predicted radius vs. mass diagram for low-mass stars as derived from the isochrones presented in the left panel of the figure. The thick solid line represents the Roche lobe of the donor star when adopting a neutron star mass of \( 1.4 - 2.0 \) \( M_\odot \). [See the electronic edition of the Journal for a color version of this figure.]

**Fig. 7.** Predicted \( M_\text{Z} \) (left) and \( M_\text{K} \) (right) as a function of the mass. Isochrones are taken from Baraffe et al. (1998) for masses \( \geq 0.075 \) \( M_\odot \) and Baraffe et al. (2003) for masses \( \leq 0.01 \) \( M_\odot \). The mismatch between isochrones in the range \( 0.075 - 0.01 \) \( M_\odot \) reflect model differences. The axes on the right-hand side are the logarithm of the upper limit to the distance (in pc) toward J00291 given by \( 5.2 - M_\text{Z}/5 \) and \( 4.7 - M_\text{K}/5 \) (see § 10.3). [See the electronic edition of the Journal for a color version of this figure.]
to heat the disk and produce an exponential decay light curve. We can estimate the distance to J00291 by assuming that the X-ray irradiation was until the knee high enough to ionize the whole disk. Shahbaz et al. (1998) following King & Ritter (1998) derived expressions for the critical X-ray luminosity necessary to keep the disk ionized everywhere. For a neutron star system they found \( L_{\text{crit}} = 3.7 \times 10^{39} R_{11}^2 \) ergs s\(^{-1}\), where \( R_{11} \) is the ionized disk radius in units of 10\(^{11}\) cm. The disk radius will be between \( R_{\text{out}} \) and the circularization radius as most of the disk mass will be accreted during the outburst event. The circularization radius is given by \( R_{\text{circ}}/a = (1 + q)(R_{11}/a)^\delta \) (see, e.g., Frank et al. 1992), where \( R_{11} \) is the distance between the center of the compact object and the inner Lagrangian point for the donor star. \( R_{11} \) can be approximated in function of \( q \) (see, e.g., Warner 1995). Using our constraints on \( a \) and \( q \), we obtain \( 2.3 \times 10^{10} \) cm \( < R_{\text{circ}} < 3.6 \times 10^{10} \) cm. From \( R_{\text{out}} \) and \( R_{\text{circ}} \) we estimate \( L_{\text{crit}} = (2.0 - 9.1) \times 10^{35} \) ergs s\(^{-1}\) and from our fit to the X-ray light curve we derive an unabsorbed X-ray flux of \( \lesssim 5 \times 10^{-10} \) ergs cm\(^{-2}\) s\(^{-1}\) at the time of the knee. Combining both results we find a distance of 1.8–3.8 kpc, in line with previous estimates by Jonker et al. (2005). Taking the apparent \( R \) and \( K \)-band magnitudes during quiescence (§3) and in line with the reddening at these bandpasses (§8), we derive from the distance module \( \log d(\text{pc}) > (5.2 \pm 0.3) - M_K/5 \) and \( \log d(\text{pc}) > (4.7 \pm 0.1) - M_K/5 \). These are lower limits to the distance toward J00291 as both donor star and disk are irradiated by the pulsar. In Figure 7 we show the predicted mass-absolute magnitude diagram for low-mass stars with ages of 0.1–10 Gyr and the mass-distance diagram derived from the distance module.

10.4. Constraints on the Neutron Star Magnetic Field

Following Burderi et al. (2002) and Di Salvo & Burderi (2003), we can place constraints on the neutron star magnetic momentum and thereby the magnetic field strength \( B \) by comparing the X-ray luminosity measured in quiescence with the expected X-ray luminosity due to residual accretion onto the neutron star or magnetic dipole radiation. The X-ray luminosity originating in these processes depends on both the pulsar spin frequency and \( B \) (see Burderi et al. 2002). Thermal emission from the neutron star may also contribute to the quiescent X-ray emission (§9) and therefore these constraints represent upper limits only. The spin period of the pulsar in J00291 is 1.67 ms (Galloway et al. 2005). The 0.5–10 keV quiescent X-ray luminosity is \( L_X \approx 3.4 \times 10^{31} \) to \( 1.3 \times 10^{32} \) ergs s\(^{-1}\) (range due to our uncertainty in the distance). Considering the above processes and using the equations derived in Di Salvo & Burderi (2003), the neutron star magnetic field is most likely less than \( 3 \times 10^8 \) G. (a neutron star with mass 1.4 \( M_\odot \) and a radius 10 km was adopted). For comparison, the magnetic field of the neutron stars in the millisecond pulsars SAX J1808.4–3658 \( (P_{\text{spin}} \approx 2.5 \) ms), XTE J1751–314 \( (P_{\text{spin}} \approx 2.3 \) ms), and XTE J0929–314 \( (P_{\text{spin}} \approx 5.4 \) ms) are constrained to be \( (1 \approx 5) \times 10^8 \) G, \(< 3 \times 10^7 \) (d/10 kpc) G, and \(< (3 \approx 7) \times 10^7 \) (d/8 kpc) G, respectively (Di Salvo & Burderi 2003; Wijnands et al. 2005).

11. CONCLUSIONS

In this paper we have presented multiwavelength observations of the millisecond pulsar IGR J00291+5934. The best source position derived from the optical and near-infrared images is \( \alpha = 00^h 29^m 03.05^s \pm 0.01^s \) and \( \delta = +59^\circ 34' 18.93'' \pm 0.05'' \) (J2000.0). From the spectral analysis of our broadband photometry we found strong evidence for excess in the near-infrared bands that may be due to synchrotron emission. We find that the most likely range for the reddening toward J00291 is \( 0.7 \leq E(B – V) < 0.9 \) (\( \approx 4.06 \times 10^{13} \) cm\(^{-2}\) \( \leq N_H \leq 5.22 \times 10^{21} \) cm\(^{-2}\)). The X-ray spectrum of the source is well fitted with a power-law model with photon index 2.4\(^{+0.5}_{-0.4}\). The unabsorbed quiescent 0.5–10 keV flux is \( (7 \pm 0.9) \times 10^{-14} \) ergs cm\(^{-2}\) s\(^{-1}\) for \( N_H = 4.6 \times 10^{21} \) cm\(^{-2}\). At least 81% of the flux in the 0.5–10 keV range is due to this model. The \((R – K)_0\) color index observed during quiescence supports an irradiated low-mass donor star and accretion disk contribution. We estimate an inclination of \( \approx 22^\circ \approx 32^\circ \), based on the H\( \alpha \) emission line profile, and we constrain the distance toward J00291 from 2 to 4 kpc. The magnetic field of the neutron star is most likely \( < 3 \times 10^8 \) G.

In contrast with the longer recurrence times for X-ray novae, several millisecond pulsars undergo outbursts in an interval of a few years. This fact opens the opportunity of obtaining a large sample of multiwavelength outburst light curves for these X-ray sources, making possible a future statistical analyses of their light curves as it has been done for the dwarf novae outbursts. The outburst light curves of millisecond pulsars may clarify the role that X-ray irradiation plays in the framework of the thermal instability model both for neutron star and black hole X-ray transients. Finally, the monitoring of an outburst should span a large spectral range to allow us to understand the emission mechanisms in these systems.

We thank Jeff McClintock and the anonymous referee for useful comments on the manuscript. M. A. P. T. would like to thank Hans-Jakob Grimm for guidance on the X-ray analysis. D. S. acknowledges a Smithsonian Astrophysical Observatory Clay Fellowship. This work was supported in part by NASA LTSA grant NAG5-10889 and NASA contract NAS8-39073 to the Chandra X-Ray Center. J. S. B. is partially supported through a Sloan Research Fellowship. The Peters Automated Infrared Imaging Telescope (PAIRTEL) is operated by the Smithsonian Astrophysical Observatory (SAO) and was made possible by a grant from the Harvard University Milton Fund, the camera loan from the University of Virginia, and the continued support of the SAO and UC Berkeley. Partial support for the PAIRETEL project was also supplied by NASA Swift Cycle 1 and Cycle 2 Guest Investigator grants. UKIRT is operated by the Joint Astronomy Center, Hilo, Hawaii, on behalf of the U.K. Particle Physics and Astronomy Research Council. We would like to thank the UKIRT Service Observing Programme for obtaining the data.
