Observable signatures of the low-z circumgalactic and intergalactic media: ultraviolet line emission in simulations

Frank, S; Rasera, Y; Vibert, D; Milliard, B; Popping, A; Blaizot, J; Courty, S; Deharveng, J M; Péroux, C; Teyssier, R; Martin, C D

Abstract: We present for the first time predictions for ultraviolet (UV) line emission of intergalactic and circumgalactic gas from Adaptive Mesh Resolution (AMR) large-scale structure simulations at redshifts 0.3 < z < 1.2, with a specific emphasis on its observability with current and near-future UV instrumentation. In the three UV transitions of interest (Lyα, O VI and C IV), there is a clear bimodality in the type of emitting objects: the overwhelming majority of the flux stems from discrete, compact sources, while a much larger fraction of the volume is filled by more tenuous gas. We characterize both object types with regard to their number densities, physical sizes and shapes, brightnesses and luminosities, velocity structures, masses, temperatures, ionization states, and metal content. Degrading our AMR grids to characteristic resolutions offered by available (such as FIREBall) or foreseeable instrumentation allows us to assess which inferences can be drawn from currently possible observations, and to set foundations to prepare observing strategies for future missions. In general, the faint emission of the intergalactic medium (IGM) and filamentary structure remains beyond the capabilities of instruments with only short-duration exposure potential (i.e. stratospheric balloons), even for the most optimistic assumption for Lyα, while the yet fainter metal line transitions (O VI and C IV) for these structures will actually remain challenging for long-duration exposures (i.e. space-based telescopes), mostly due to their low metallicities pushing them more than three orders of magnitudes in brightness below the Lyα radiation. For the bright, circumgalactic medium, the situation is much more promising, and it is foreseeable that in the near future we will not only just detect such sources, but also the combination of all three lines in addition to velocity information will yield valuable insight into the physical processes at hand, illuminating (and discriminating between) important mechanisms during the formation of galaxies and their backreaction on to the IGM from whence they formed.

ABSTRACT
We present for the first time predictions for UV line emission of intergalactic and circumgalactic gas from Adaptive Mesh Resolution (AMR) Large Scale Structure (LSS) simulations at redshifts 0.3<z<1.2, with a specific emphasis on its observability with current and near-future UV instrumentation. In the three UV transitions of interest (Ly\textsc{a}, OVI and CIV) there is a clear bimodality in the type of emitting objects: the overwhelming majority of the flux stems from discrete, compact sources, while a much larger fraction of the volume is filled by more tenuous gas. We characterise both object types with regard to their number densities, physical sizes and shapes, brightnesses and luminosities, velocity structures, masses, temperatures, ionisation states, and metal content. Degrading our AMR grids to characteristic resolutions offered by available (such as FIREBall) or foreseeable instrumentation, allows us to assess which inferences can be drawn from currently possible observations, and to set foundations to prepare observing strategies for future missions. In general, the faint emission of the IGM and filamentary structure remains beyond the capabilities of instruments with only short duration exposure potential (i.e. stratospheric balloons), while the yet fainter metal line transitions (OVI and CIV) for these structures will actually remain challenging for long duration exposures (i.e. space-based telescopes), mostly due to their low metallicities pushing them more than three orders of magnitudes in brightness below the Ly\textsc{a} radiation. For the bright, circum-galactic medium (CGM) the situation is much more promising, and it is foreseeable that in the near future we will not only just detect such sources, but the combination of all three lines in addition to velocity information will yield valuable insight into the physical processes at hand, illuminating (and discriminating between) important mechanisms during the formation of galaxies and their backreaction onto the IGM from whence they formed.

1 INTRODUCTION

Both inventories of the cosmic baryons budget (Fukugita et al. 1998; Fukugita & Peebles 2004), and cosmological simulations (Cen & Ostriker 1999; Davé et al. 2001)
Beyond the baryon accounting issue itself, this approach is providing new insights into important aspects of cosmic evolution, specifically about the low fraction of baryons (about 6%) that have made their way into stellar populations of galaxies, the interdependence between the IGM and galaxy evolution, and the crucial role of baryons circulating in and out of galaxies.

The exploration of matter in the IGM at densities below the mean density is naturally performed through quasar (or other bright background sources) absorption-line studies, and has a long history of spectacular successes. At low redshift, in the domain of tracers of the Warm-Hot intergalactic medium (WHIM), this is now culminating in observations with the Cosmic Origins Spectrograph (COS) on board of HST (e.g. Narayanan et al. (2011); Savage et al. (2011)).

Absorption line studies are, however, traditionally limited by a number of factors, such as the need for bright background sources, the difficulty of exploring perpendicular to a line of sight, and the difficulty of finding background sources for investigating a specific object. In addition any improvement in sensitivity requires an increase of collecting area. Emission line observations, as discussed by Hogan & Weymann (1987) and Gould & Weinberg (1996), have therefore been considered as an alternative approach. They are not affected by the issue of background sources and, depending on the observed solid angle, are less demanding than absorption techniques in terms of collecting area. In this vein, e.g. Rauch et al. (2008) have performed a very long exposure with VLT in order to detect Lyman α emission from matter at the transition from ionized gas to neutral, self-shielded gas.

Exploiting a variety of simulations, predictions have been made for the possible signatures of structure formation and feedback processes in terms of emission lines over a range of redshifts. Focusing on hydrogen as the naturally most abundant species, Furlanetto et al. (2004, 2005); Kollmeier et al. (2010) and references therein, predict Lyα emission from IGM gas at 0 \( \leq z \leq 5 \), and discuss various mechanisms for its origin (reradiation of absorbed ionising photons from the metagalactic UV background; radiative cooling of shocks during the assembly of gravitationally bound objects; interaction of strong winds with the surrounding IGM). Furthermore, these authors also stress the difficulty to discriminate between these, in addition to the complication that galaxies themselves emit in Lyα. Bertone et al. (2010) and Bertone et al. (2010) trace a large suite of metals in different ionisation stages through their SPH simulation in combination with state of the art gas cooling prescriptions to track their emission both in the soft-X rays as well as in the (restframe) UV over a similar redshift range as above(0<z<5). Of particular interest are their notions that the transitions in CIII, CIV, SiIV and OVI are bright enough (>1000 photons/(s cm² sr)) to allow for a detection with current technology (‘in the near future’) in gas of moderate overdensities (\( \delta \geq 100 \)) that has been enriched to metallicities \( Z > 0.1Z_{\text{Solar}} \). They caution, however, that hence these emission lines are biased tracers of the baryons, but still provide good tools to detect gas cooling onto or flowing out of galaxies.

In this paper, we follow a similar line of investigation for Lyα, CIV and OVI emission over the redshift interval 0.3<z<1.2, but go one step further in the detailed effects of observability with current and/or near-future instrumentation in the UV. We clearly highlight the limitations posed by the detectors’ spatial resolution, and stress the importance of taking the velocity structure of the emitting gas into account. We run source finding software in simulated data-cubes on grids resembling a typical instrumental set-up, and are for the first time able to characterise potentially detectable structures with respect to their brightness, luminosities, masses, surface and volume densities, sizes and morphologies. There is a clear delineation (in Lyα) between the very diffuse and extended filamentary structures tracing the true IGM, and ‘haloes’ surrounding the bright and massive nodes of the Cosmic Web, which are more compact (<200 kpc/h in diameter) and much brighter than the filamentary sheets.

The paper is organised as follows. We briefly discuss the simulations in Section 2, highlighting the methods to calculate the gas emissivities in (2.2) and add a description how to arrive at an observable data cube in (2.4). In section 3 we take a first look at these cubes in all three emission lines we are primarily interested in (Lyα, CIV, and OVI), and discuss general features of the emission in terms of brightness distribution functions and spatial extent, while sections 4 and 5 provide a closer look at the extended, filamentary structures and the compact, bright sources, respectively. Before concluding in section 6 we discuss the implications of our findings in terms of observing strategies and optimal technical instrument specifications in section 6.

Throughout the paper we use a ΛCDM cosmology with the results of WMAP5 (see next section for detailed parameters).

2 SIMULATIONS

2.1 Cosmological simulations

The high-resolution cosmological simulation investigated in this article is part of the BINGO! simulation suite. It was performed at the CINES computational center with the RAMSES Adaptive Mesh Refinement (AMR) code

\footnote{BINGO! is a 4-year project of the “Agence Nationale de la Recherche” (ANR), started in 2009. The consortium of three partner institutes (Marseille, Lyon, and Paris) specifically investigates both theoretically and observationally the physical processes of structure and galaxy formation with an emphasis on their interactions with the IGM and CGM.}
hydrogen density and temperature, assuming the same uniform ionizing background as adopted for the simulations and hence being self-consistent regarding this detail. We have used the c8.00 version of the spectral synthesis code Cloudy, last described by Ferland et al. (1998), to compute the line emissivities of a plasma submitted to an incident continuum. The line emissivities of interest in this paper are Lyα at 1216 Å, O VI at 1032/1038 Å and C IV at 1548/1551 Å. Grids have been generated at the redshifts z=0.35, 0.76 and 1, and for each redshift, the incident continuum used in Cloudy is the same ultra-violet background used in the simulation at the same redshift. Practically, these specific redshift values have been adopted in order to place the redshifted lines in the unique narrow spectral UV window at 2000 Å accessible from stratospheric balloon-borne experiments such as FIREBall; in the following we will explore the redshift influence since our goal is to understand gas emission over the redshift range 0.3 - 1.

Grid points are computed for temperatures between $3 \times 10^3$ K and $3 \times 10^8$ K every $\Delta \log(T/K) = 0.01$ and for densities between $n_H = 1.778 \times 10^{-6}$ and $n_H = 1$ cm$^{-3}$ every $\Delta \log(n_H/cm^{-3}) = 0.5$. Two sets of grids are calculated, one assuming the plasma to be in photoionization equilibrium with the UV background and another one assuming collisional ionization equilibrium. The grids are computed at solar metallicity and the emissivities of each gas cell is rescaled according to their gas metallicity. We use the “no induced processes” of Cloudy (for an explanation for this choice see e.g. Furlanetto et al. 2004 and the following treatment of the photon pumping).

### 2.3 Self-shielding

Our simulation assumes a uniform ionizing background which heats the gas as if it were optically thin everywhere. This introduces two potentially important limitations to our predictions of gas emissivities: (i) the ionization state of self-shielded gas is not accurately described (the neutral fraction is under-estimated), and (ii) the temperature of self-shielded gas may be over-estimated (heating from the UV background is active everywhere).

Self-shielding of gas to cosmological (inhomogeneous) ionizing background is an extremely complex question which can really be addressed only with simulations which jointly solve for radiative transfer and hydrodynamics. There has been substantial work to accomodate for that and describe a posteriori the effect of self-shielding, either in the perspective of absorbers (e.g. Schaye 2001, Pontzen et al. 2008, and references therein), “cooling” radiation (Furlanetto et al. 2004, Faucher-Giguère et al. 2011, e.g.), fluorescence (Kollmeier et al. 2010), or of course in the perspective of high-redshift reionization (e.g.)

3 http://www.nublado.org

4 In practice, regions with $n_H > 0.1 cm^{-3}$ (and $T < 10^4 K$), are described with a polytropic equation of state, and are thus effectively self-shielded since their temperature is solely a function of their density.
Figure 1. The relative flux distribution for the simulated 100 Mpc/h box in the log T - log n_H bins (coloured phase-space diagram), and the Lyα volume emissivity (black solid lines, in units of erg/(s × cm^3)) as function of hydrogen density and gas temperature using only photo-ionisation equilibrium (PIE, left panel) or collisional ionisation equilibrium (CIE, right panel) assumptions at a redshift of z=0.75. In addition, the location of the cuts used to delineate various scenarios for the self-shielding treatment is indicated by the dashed lines plus the two rectangular boxes on the lower right (for details, see text). It is clear that for Lyα emission the exact location of those cuts plays a vital role in determining the total emission, as gas with high density and T ∼ 10^4 K dominates the emission. Note that in this and the following plots, the choices of redshifts stem from our restriction to a constant wavelength coverage over a well-defined UV regime of a putative instrument, in order to be realistically illustrative.

Self-shielding thresholds
Because we are interested in emission of IGM or CGM gas only, we first discard the gas with n_H > n_{ISM} = 0.1 atoms/cm^3. In our simulations, this gas is star-forming ISM. In the approach by [Furlanetto et al. (2004)], e.g. it is decided that gas with n_H > n_{SS} and T < T_{SS} is self-shielding. Here, T_{SS} is a temperature above which the emitting species (e.g. HI) is mostly ionized by collisions (e.g. at T_{SS} ∼ 10^4.5, H is mostly in the form of H_ii, so that the gas becomes transparent to H_i-ionizing photons). Above T_{SS}, the emitting species cannot self-shield, and photo-ionization becomes dominant. n_{SS} is some typical density at which self-shielding should be effective. In reality, self-shielding is a column density effect, and using a cut on density only is bound to be a poor proxy. Here, we have in addition chosen another, more physically motivated approach. We assume that only gas at a sufficiently high pressure self-shields, and take the thermal pressure (P/k ∼ nT) as a proxy for the total pressure that guarantees hydrostatic equilibrium (including e.g. magnetic pressure, cosmic ray pressure etc.). Empirically, it is found that a threshold of P/k = 155 cm^3 K results in an HI density of ρ = 6.1 × 10^6 hM⊙ Mpc^-3 (at z=0, [Popping et al. (2009)]), a value that is similar to the value observed in Zwaan et al. (2003) for their self-shielding thresholds. Furthermore, only gas whose radiative recombination time (τ_{rec} ∼ T^4 × n_e) is shorter than the sound crossing time (τ_s = R/C_s, with the sound speed C_s ∼ T_0^{1/2} and the relevant length scale R) can recombine, and hence self-shield. A priori, it is not clear which length scale should be chosen, here we have assumed two values (R=1.0 and R=0.1 kpc). The densities and temperatures delineated by these boundaries are within the ranges given in the literature (e.g. [Zwaan et al. (2003); Weinberg et al. (1997); Wolfire et al. (2003) and Pelupessy (2005)]). For the metal line transitions similar arguments...
Figure 2. Same structure as in Figure 1 now showing OVI at a redshift of z=1.0. Note how here (and in the following plot for CIV) the area of main emissivity shifts to much higher temperatures (above $10^5$ K), and thus the exact location of the self-shielding cut does not play an important role anymore for determining the total flux.

2.4 Other emission processes: photon pumping for Lyα radiation

There is deliberately no light emission associated with the formation of stars in this simulation. However, the UV background used here (Haardt & Madau 2001), does include on top of the QSO emission an integrated contribution from stars, but only above the Lyman limit (i.e. zeroed escape fraction below that limit). Due to the large cross-section for absorption of hydrogen gas at Lyman line wavelengths, continuum photons from the non-ionizing background can be scattered when they are redshifted to the Lyman resonance lines. This process, often coined ‘photon pumping’, has not been accounted for by our simulation.

With an isotropic background, as assumed here, this pumping does not have a net effect for Lyα emission, as it simply consists of a redirection photons in a medium that is permeated by an already isotropic radiation field - the only true additional contribution may arise from the conversion of higher order Lyman line photons into Lyα photons. Furlanetto et al. (2004) estimate this contribution to remain below the level of a few percent. Hence, our calculations of the gas emissivity explicitly avoid the effects of photon pumping by turning this feature off in CLOUDY, as suggested by Furlanetto et al. (2004). Note, however, that

Emissivity of Self-shielding gas

We use two simple scenarios to compute the emissivity of the self-shielding gas. Either we assume this gas to be in collisional ionization equilibrium (CIE) at the temperature and density provided by the simulation and use CIE tables to predict its emissivity. Or we argue that had the simulation taken self-shielding into account, the gas would be at much lower temperatures than predicted, and would simply not emit even in CIE. In that case, we set the emissivity to zero.
the situation changes locally, if the UV radiation field is anisotropic and potentially of different spectral shape than the general background - as it can be imagined near UV bright galaxies. Properly modelling the photon pumping contribution (or actually tracing the continuum photons responsible for it on their paths through the simulated cubes) is beyond the scope of this paper, but we have performed calculations with simplified assumptions to judge the importance of it (cf. 6.2). From these, we conclude that indeed enhancements of the flux over the emissivities calculated here of an order of magnitude are possible in the proximity of UV bright sources.

2.5 Simulated Observations

We construct mock data cubes from our simulations in two steps: first, we build a pre-observation light-cone at the full AMR resolution, and second, we convolve this light-cone with instrumental effects.

Pre-observation light-cones

The typical geometry of the light-cones we wish to produce is that of a pencil beam, i.e. a cone with a radial extent much longer than the size of our simulation (typically \( \geq 5 \) times) and an angular extent probing scales less than a tenth the size of our simulation at most. Another point in consideration is that we are interested in emission from diffuse intergalactic gas, which can produce extended signal on scales up to a few tens of Mpc. It is thus important to preserve the continuity of the gas density field in the light-cones. We use the MOMAF software (Blaizot et al. 2005) to cut a light-cone out of our simulation. MOMAF takes care of replicating our (periodic) simulation at will and to cut light-cones in any direction relative to the axis of the box. In order to preserve continuity, we chose not to use the random tiling technique and to build light-cones out of one simulation output only. This avoids both redshift and replication discontinuities (see Blaizot et al. 2005 for details). We then chose lines of sight by carefully selecting angles for light-rays in order to minimize replication effects.

In practice, we build three different types of data cubes (see below, one for each emission line of interest). For this, we use the snapshots, i.e outputs at \( z \sim 0.35 \) (resp. 0.75, 1.04) for CIV (resp. HI, OVI). We have checked that our conclusions are not changed if we use slightly different snap-
Table 1. Different models for the emissivity of the gas in the light cones. Generally speaking, we divide the parameter space in loci that exhibit either strictly no emission, or an emissivity is calculated by applying CLOUDY with either photo-ionisation equilibrium (PIE) or collisional-ionisation equilibrium (CIE). The number indicated for each model corresponds to the one used in the different plots. Models 2 and 3 follow closely the procedure and values suggested by Furlanetto et al. (2004), while models 4 and 5 allow for a ten times higher limiting density threshold for CIE or PIE. Models 6-9 involve the pressure and timescales for recombination and sound crossing.

| Cut | Zero emissivity | PIE emissivity | CIE emissivity |
|-----|-----------------|----------------|---------------|
| SF cut | $n_H \geq 0.1$ | $n_H < 0.1$ | - |
| +CIE | $n_H \geq 0.1$ | log $T > 4.5$ OR | log $T < 4.5$ AND |
| +cut | $n_H < 5.1 \times 10^{-3}$ (Lyα) | $n_H > 5.1 \times 10^{-3}$ (Lyα) | - |
| +CIE x10 | $n_H \geq 0.1$ | log $T > 4.5$ OR | log $T < 4.5$ AND |
| +cut x10 | $n_H < 5.1 \times 10^{-2}$ (Lyα) | $n_H < 5.1 \times 10^{-2}$ (Lyα) | - |
| R=1 kpc + CIE | $n_H \geq 0.1$ | P/k $> 258$ OR $\tau_{rec} > \tau_s$ | P/k $> 258$ AND $\tau_{rec} < \tau_s$ |
| R=1 kpc + cut | P/k $> 258$ AND $\tau_{rec} < \tau_s$ | P/k $< 258$ OR $\tau_{rec} > \tau_s$ | - |
| R=0.1 kpc + CIE | $n_H \geq 0.1$ | P/k $< 258$ OR $\tau_{rec} < \tau_s$ | P/k $> 258$ AND $\tau_{rec} < \tau_s$ |
| R=0.1 kpc + cut | P/k $< 258$ AND $\tau_{rec} < \tau_s$ | P/k $< 258$ OR $\tau_{rec} > \tau_s$ | - |

1 The values change with different redshifts, hence: $n_H > 7.1 \times 10^{-3}$ (OVI) and $n_H > 2.7 \times 10^{-2}$ (CIV).
2 $n_H > 7.1 \times 10^{-2}$ (OVI) and $n_H > 2.7 \times 10^{-1}$ (CIV).
3 For OVI at z>1.0, we apply P/k(z) = 356, and for CIV at z<0.35 P/k = 135 as dividing line.

Observed data cubes

As an instructive example, we chose to mimick the instrumental characteristics of FIREBall (Tuttle et al. 2010; Millard et al. 2010). We will discuss alternative choices of angular or spectral resolutions in Sec. 5, but note here that current or near-future UV missions are of quite similar layout. While focusing on the FIREBall spectral coverage forces certain specific redshift choices for the three lines in question, it does also allow us to check on differences regarding the cosmic evolution over that redshift span (0.35 < z < 1.1).

In order to produce observed data cubes from of our pre-observation catalogs, we proceed in 3 steps. First, at the full AMR resolution, we compute the luminosity of each cell according to the various models described in Sec. 2. Second, we derive each cell’s flux contribution to a regular grid (in $\alpha$, $\delta$, and $z$) with better resolution than the typical angular and spectral point-spread function. Third, we then convolve these in the spectral as well as the spatial dimensions to arrive at the desired final resolution in angular direction we apply a sharp disk of an 8 arcsec diameter, and in the spectral direction we convolve with a Gaussian of FWHM = 2.25 pixels $\sim 0.56$ Å, and finally save the convolutions on a regularly gridded data-cube.

We have generated 300 of such fields of view with an approximate 3x3 arcmin$^2$ FOV (similar to FIREBall’s FOV) in order to assess the effects of cosmic variance (e.g. for the construction of the PDFs). Furthermore, for instructional purposes, we have specifically chosen 3 sightlines (for each transition and redshift) with a larger FOV: one towards a field containing a known very massive Dark Matter structure to represent a best case-scenario for ‘bright’ sources, one which contains an example for a bright, large filamentary structure, and another one as the ‘best’ compromise between those two criteria. These fields cover a field-of-view (FOV) of fixed size (900 x 900 arcsec$^2$), and fixed spectral coverage (270 Å), thus creating cubes of different volumes depending on the specific redshift. The selection of these sightlines, in fact, used PDFs (see below) from fields of smaller FOV, in order to determine their brightness distributions.

Figures 1 to 3 show the phase space diagrams of the simulation, each cell weighted by its luminosity in the Lyα, OVI or CIV transitions. Note how dominant the high density regions (log $n_H > -2$) are in these, as emissivity (denoted by the solid, curved lines) scales with $n_H^2$. It is immediately obvious that the treatment of self-shielding is very important for the Lyα estimates, while it plays less of a role for the metals, which emit most of their light from gas at temperatures $> 10^5$ K.

3 GENERAL FEATURES OF THE LINE EMISSION

Even a casual visual inspection of the line emission inside the simulated cubes (cf. Fig. 1) reveals a clear bimodality in the types of emitting regions. There are on the one hand bright sources, spatially confined to small areas, but extended in wavelength due to the gas being spread out in velocity space. In the vicinity of these, and connecting such regions, there are filamentary structures, which are much fainter, more extended spatially and affected less...
by the velocity dispersion of the gas. We will discuss the specific properties of these two different classes of emitters in the next two sections, but focus here first on general implications.

Figures 5, 6 and 7 show the probability distribution functions (PDF) of the voxels’ emission in Lyα, OVI and CIV, weighted by volume. The solid lines represent the PDFs based upon the full AMR resolution, while the dashed lines are PDFs calculated after resampling of the data cubes with a grid of 3 arcseconds spatially and 0.25 Å spectrally, subdividing the simulated cube smoothed with the resolution of $8 \times 8$ arcsec$^2$ and 0.56 Å as described earlier (resembling the FIREBall instrument specifications). Note that unlike e.g. the PDFs presented by Bertone et al. (2010) and Furlanetto et al. (2004) these are PDFs based upon the full 3D voxel distribution, i.e. we do not collapse along one axis and derive the distribution on the resulting 2D images of such slices. Hence, a comparison of the curves is not straightforward. The various cuts to deal with the self-shielding gas are indicated by the different colours. Obviously, the two extreme distributions are achieved when the cuts are most lenient or most severe in excluding gas located in the parameter space that exhibits the highest emissivity. The former happens when we choose to apply the CIE case for $R=0.1$ kpc (denoted as example 8 in Table 1), the latter is achieved by neglecting all emission for $R=1.0$ kpc (example 7). In the following, and in various graphs, we will refer to these two extreme scenarios as CUT7 and CUT8, respectively.

A decrease in resolution has a dramatic effect on the brightest areas, but leaves the distribution unchanged for surface brightnesses less than $\sim 1$ CU. The upward shift of the plateau ranging from about $2.0 \leq \log \text{CU} \leq 7.0$ at the AMR level to a similar plateau with a lower cutoff high surface brightness, but a higher volume fraction at the lower resolution clearly indicates that the brightest pixels are strongly ‘clustered’, i.e. form collectively the bright, spatially compact sources. These bright regions are rare: even for the resampled cubes they do not cover more than 0.1% of the volume, but carry almost all of the light emitted in all three lines. The various cuts dealing with the self-shielded gas allow us to bracket the expected emission. Note that in the case of Lyα the cut-off values for the brightest sources change by a factor of 100, a direct reflection of the fact that this is the location of the parameter space where the emissivity for Lyα peaks (cf. Fig. 1). In contrast, as expected, the exact treatment of the self-shielded gas has very little effect on the bright end of the surface brightness distributions for the OVI and CIV line emission.

Figure 8 shows two PDFs for Lyα at the redshifts of $z=0.75$ and $z=0.35$. Note that there is by no means a simple $(1+z)^3$ evolution at all, as may be expected from sheer cosmological expansion effects (meaning that the lower redshift values should exceed the higher ones by a factor of about 3), but a more complex evolution. The faint emission peak e.g. becomes even less bright, mostly due to the change in the ionising radiation field weakening towards lower $z$. The brighter regions beyond the knee in the distribution, however, do become brighter at the lower redshift. Hence, the redshift evolution of the surface brightness distribution is a complicated function, whereby geometric cosmic expansion and true evolutionary source effects combine in a non-trivial fashion. In any case, the evolution expected from redshift changes surveyed here is probably small compared to the uncertainties introduced by the self-shielding treatments.

4 BRIGHT, COMPACT SOURCES/CGM

4.1 Introduction to the source finder

The simulations with the reconstructed distribution of Lyα, CIV and OVI contain bright objects with extended environments connected by filaments spanning up to the whole spatial scale of the simulation output. Features in the simulated outputs only represent circum- and intergalactic gas, as all the star forming gas and gas in the galaxies has been removed using thresholds as described in 2.2. To extract objects from the simulated cubes, we have used the source finding algorithm Duchamp (Whiting 2008), an algorithm that has specifically been developed to detect objects in 3D radio observations that typically have dimensions of RA, DEC and velocity. The software is however very flexible and can be used for any kind of three dimensional dataset.

The simulation outputs tailored to the spectral and angular resolution specifications of FIREBall (see earlier) were used as input for Duchamp. Within Duchamp, a parameter input file constrains the properties of a possible detection. For all objects a requirement has been set, that detections consist of at least two adjacent voxels in the spectral direction. Because of the oversampling in the spectral direction by about a factor two, this is the minimum size an object can have.

Within Duchamp objects were sought using two different thresholds. The first threshold represents the minimum peak flux a feature should have to be accepted as a compact object. In the reconstructed Ly-α cubes compact objects can be distinguished by their large peak flux. The brightest regions in the filaments have typical values of the order of $\sim 10$ CU, therefore the first threshold for Ly-α is chosen at 100 CU. Once the location of bright and compact features has been determined, the objects are grown in size by adding adjacent voxels until a second (lower) threshold has been reached. By using two different thresholds we can isolate compact objects down to a relatively low flux threshold which is below the peak flux of extended filamentary structures. For Ly-α the second threshold is chosen at 10 CU. Although detections could be extended to lower flux thresholds, this would increase dramatically their size and include parts of filaments or possibly even

---

6 $1 \text{CU} = 1 \text{photon s}^{-1}\text{cm}^{-2}\text{sr}^{-1}\text{Å}^{-1}$

7 The algorithm is described and can be obtained here: [http://www.atnf.csiro.au/people/Matthew.Whiting/Duchamp/](http://www.atnf.csiro.au/people/Matthew.Whiting/Duchamp/)
merge them, without adding significant amounts of flux.

For each transition the threshold fluxes were determined empirically by carefully inspecting the cubes, the exact values are given in table 2. The sharp edges of the source regions make the number of the detected sources largely insensitive to the threshold values, as it is possible to choose a value for the second threshold that allows for picking up a large fraction of the total light inside the simulated volume while ensuring that there is little source merging. The same flux thresholds have been used for all self-shielding cuts, since the selected cuts only affect the densest regions, and even the most severe such cut does not prevent detection with the parameters chosen here.

| Element | threshold 1 [CU] | threshold 2 [CU] |
|---------|-----------------|-----------------|
| Ly-α    | 100             | 10              |
| OVI     | 1               | 0.5             |
| CIV     | 0.5             | 0.05            |

4.2 Source properties: Space density, luminosities, sizes, shapes, spectral information

The number, and hence space density (not the flux) of those sources in Ly-α is very robust and almost independent of the self-shielding cut criteria and the specific parameters we

---

For the harshest cut criteria, a select few (in the extreme case 4 out of >1000) Ly-α objects fall below the minimum detection.
Figure 5. The probability distribution function (PDF) of the voxels' line emission in Lyα for $z \sim 0.75$, weighed by volume (left panel; i.e. we simply count all the cells' volume per certain brightness bin and divide by the total survey volume in order to derive the fraction per bin). Note that this is hence a 'true' pdf in the sense that we are using the complete 3D cube, and do not collapse along one dimension (in contrast to e.g. the PDFs by Furlanetto et al. [2004] or Bertone et al. [2010], whose results are based on the pixels of an image). The sudden change in slope when reaching the plateau around a few CUs from the low surface brightness side is indicative of reaching a different population, which can - as detailed in the text and Figs. 11 and 12 - be equated with bright compact sources. The effect of resampling from the AMR refinement level (solid lines) to the observationally dictated resolution (dotted lines) is a dramatic loss of the highest surface brightness objects. Note also that the choice for different treatment of self-shielding results in factors of 10-100 for the brightest spots. Bright sources are rare, but carry almost all of the light: $10^{-4}$ of the volume after resampling. The most important aspect regarding the resampling, however, is that the very brightest spots still remain within the range of capabilities of an instrument with current technology, as discussed in section 6. The right panel shows the PDF weighed by mass, the differential mass distribution being the large plot, and the inset representing the cumulative distribution. It is clear that being able to trace a sizeable fraction of the baryonic mass ($\sim 10\%$), an instrument needs to go down to a surface brightness limit of a few CU.

use for the detection algorithm, and thus a strong prediction of the simulation. We find a number density for the Lyman α bright sources of $\eta(\text{Ly} \alpha, z = 0.75) = 3.8 \times 10^{-3} \text{(Mpc/h)}^{-3}$. Interestingly, the densities for bright sources in CIV and OVI are not very different: $\eta(CIV, z = 0.37) = 2.48 \times 10^{-3} \text{(Mpc/h)}^{-3}$, and $\eta(OVI, z = 1.1) = 17.3 \times 10^{-3} \text{(Mpc/h)}^{-3}$. In these cases, however, the detection algorithms' parameters do lead to a fraction of the faintest sources being dropped, i.e. it is not possible to find good combinations of the 2-fold threshold approach that isolates the point sources without introducing overlaps and/or losses. As those sources are too faint to be detected in any realistic scenario (see paragraph 6.2), we have not tried to fine-tune the detection algorithm in order to better isolate these objects. In any case, of much more importance, even for Lyα compact sources, are the restrictions imposed onto us by the simulation’s mass and spatial resolution. We have performed tests regarding conversion with earlier, lower resolution simulations, and found that we are ‘complete’ to a luminosity of $\log L(\text{Ly} \alpha) \geq 41.5$ (at $z=0.75$; resp. $41.2$ for $z=0.35$), $\log L(OVI, z=1.1) \geq 40.5$, and $\log L(CIV, z=0.35) \geq 40.0$ (see below for calculation of the source luminosities). That is, increased resolution may result in producing a higher fraction of areas that had fallen underneath the threshold criteria used here in the lower resolution simulations, due to the strong non-linearity of the brightness as a function of density and temperature. Thus, for all transitions, the numbers quoted here are strictly lower limits. Furthermore, we remind the reader that we have extracted these sources in three different cubes for each transition that were not randomly chosen, but care was taken to select sightlines that do show large-scale structure. While this procedure resembles in some respect the target selection for a real observation, we nonetheless point out that cosmic variance is an additional factor in producing fluctuating number densities for which we have not accounted here.

How big are the objects and what are their shapes? The answers to these questions are not quite as straightforward as one may naively assume. While the spatial extent perpendicular to the sightline in our cubes immediately translates to a size measurement, the coordinates along the sightline have the additional complication that the pixels we analyse have their peculiar velocities imprinted on them. As a first step towards estimating the sizes of the sources we have hence constructed small cutouts of...
Observable Signatures of the low-z Circum-Galactic and Inter-Galactic Medium: UV Line Emission in Simulations

Figure 6. Same plot as Figure 5, but this time for OVI emission at \(z=1.1\). In contrast to the Ly\(\alpha\) radiation, here most of the cube's volume is filled by gas in a regime (low temperatures, low densities and extremely low, if not zero, metallicity) that does emit very few, if any photons, hence the integral over the surface brightness range depicted here does not add up to unity. Note how much less important the cuts for self-shielding are regarding the distribution of the brightest voxels in the metal line, indicating that the main contribution to the flux in OVI and CIV, see Figure 7, is emitted by gas with temperatures higher than the limits imposed by our self-shielding treatment. Note also how the some of the curves are exactly overlapping, as the self-shielding cuts do not affect any areas contributing to the surface brightness levels shown here.

Figure 7. Same as Figure 6 but for CIV at \(z=0.35\).

the cubes (centered on the coordinates found by Duchamp as central pixels) and summed them up along the full extent of the sources (given by their minimal and maximal estimate for the \(z\) coordinate in Duchamp). We then try to fit a simple 2-D Gaussian to the light profile of such a collapsed image. In the majority of the cases the fitted FWHMs of the Gaussian (in \(x\) and \(y\) direction) are of a similar size, indicating that the underlying light profiles can be reasonably well described by the average of them for a crude size measure (Figure 11 shows an example of such an object in Lyman \(\alpha\)). For some objects, however, this blunt approach fails because their spatial (and often also
velocity, see below) structure is more complicated. Figure 12 highlights a source that shows multiple bright cores, and even a hint for ‘bridges’ between them.

Figure 8 shows the distribution of luminosities of the distinct sources detected by Duchamp in the Lyα and metal line cubes, smoothed to FIREBall resolution, and according to the two most extreme treatments for the cells containing self-shielding or star-forming gas (CUTS 7 and 8). For Lyman α, the luminosities of the objects picked up by Duchamp is strongly dependent on the specific treatment of the observed cubes with regards to the self-shielding and star-forming gas, as figure 9 clearly demonstrates. The various cuts introduced earlier lead to luminosities for the same objects straddling almost a factor of 100 in brightness in the extreme cases. Hence, for the Lyα sources we can only bracket the luminosities assuming either the severe cuts (resulting in a median luminosity of log L [erg/s] = 40.9 ) or the optimistic cuts (median log L [erg/s] = 41.8). The estimates for the OVI and CIV emission, on the other hand, are much more robust, because - as we have seen earlier - the cuts we introduce are not affecting pixels of the highest emissivity in these two transitions (median log L[erg/s] = 39.2 and 38.5 for OVI and CIV, respectively). Notice also, that the distributions for the bright objects in the metal lines are much broader than for Lyman α. This is not, as we will see in the next paragraph, due to a broader distribution in sizes of these objects, but a result of a larger spread in the peak brightness of the most dominant pixels. Overall, the objects observable in OVI and CIV are in general at least 1.5 orders of magnitude less luminous than the HI sources, but are spread fairly evenly over almost 3 decades. Keep in mind, however, that for an assessment of their observability the much lower redshift for CIV and hence luminosity distance does help (yielding a factor of ~7 in surface brightness).

In Figure 10 we show the relation between the luminosities and the FWHMs (averaging the x and y components) of the compact objects - note that we flagged out the obvious failures of the simple fitting. While the majority of the sources lie between about 50 and 100 kpc (proper), there are a few exceptions that can reach up to the enormous size of 300 kpc. The sharp low cutoff boundary (most easily visible for HI and OVI) represents the minimum FWHM of 2 pixels, i.e. is a result of the image resolution. While there is a general trend for the more luminous objects in Lyman α to be also bigger, interestingly the reverse seems to hold for the CIV bright sources (and potentially also for OVI). Currently, we have no explanation for this anticorrelation in size vs. luminosity for the metal line bright objects.

When we instead collapse the 3D cutouts from above along the two spatial axes perpendicular to the line of sight, we can obtain some information on the velocity structure of the emitting gas. Figure 11 shows the profiles along the z direction for the a representative selection of bright sources in OVI along with their appearance in the spatial coordinates (green boxes) Here we plot the aggregated flux densities (integrated over the maximum

Figure 8. Similar to Figure 5, but now emphasising the redshift evolution for the Lyα emission from z=0.75 to z=0.35, and employing the two most extreme treatments for the self-shielding gas. The peak of the distribution shifts to lower surface brightnesses with decreasing redshift, mostly due to a weakening UV-background and dilution of the gas because of cosmic expansion. The bright, isolated areas show a slight increase in their brightness, but not as much as expected from a simple (1+z)^4 scaling, rendering the evolution a more complicated function with redshift, density, temperature, and environment contributing to the complexity.
source extent in x and y) versus the pixels’ location in the cubes along z. If we assume the stretching in wavelength to be almost exclusively due to the peculiar velocities of the gas particles, we can translate the spectral extent into a velocity plot. Highlighted are four different scenarios into which we can group our objects. The zero velocity bin is defined arbitrarily to be the one with the highest flux, and we normalise by dividing through this peak flux. The top left panel shows the most common profile: a single peak (representative of about 65% of the objects in Ly$\alpha$ and OVI, but less than half in CIV—see table 3). If we fit these single peak profiles with a Gaussian, the FWHM ranges between 150 and about 400 km/s, with the bulk of them between 200 and 300 km/s. The next largest group (25-30% for all transitions) exhibits double profiles, which themselves can come in at least three different flavours: the majority has two peaks of almost equal height, and a trough in between that never reaches zero flux (right upper panel). Some of the objects, however, have one peak rather dominant over the other one ($\geq$ a factor of 2 in maximum flux). These can be further divided into sources where there is either no gap of zero flux in between them, or where there is a separation (but less than 200 km/s). Note that for most of these objects the spatial structure is still indicative of one single object, as in this example, but for a few sources it is clear that there are two distinct features that are responsible for the double peak in the velocity profile. A third category of objects has a multitude of different peaks, of varying heights with or without gaps of zero flux. While these represent less than 5% for the Ly$\alpha$ and OVI emitting sources, they correspond to 10% of the objects for the CIV emission. While the velocity spread is in most cases for all of the transitions confined to less than $\pm$400 km/s from the zero velocity bin, there are a few, rare cases where the whole structure can span almost 1300 km/s (see lower left and right panels). Those two examples again demonstrate that these complicated velocity profiles may be the result of many bright sources overlapping in
the subcube extracted to derive the velocity profile (lower right), but need not be necessarily (lower left). While the former velocity profiles then can be readily explained by an overlap of a few single source profiles, the latter cases may be resulting either from multiple sources situated along the line of side, or be intrinsically more complex, possibly due to the imperfections of the extraction method (i.e. not taking into account spatial structures). Those latter cases, however, are only exhibited by a tiny minority of the sources (<2% in all transitions).

4.3 Comparison with Lyα observations and origins of the bright Lyα emission

Our bright and compact sources, as displayed in Fig. 12 and with properties summarised in table 3, reach Lyα luminosities and space densities comparable to or larger than those obtained for the so-called Lyα emitters (LAEs) revealed by a number of spectroscopic or narrow band imaging surveys at high redshifts (e.g. Ouchi et al. 2008 and references therein). This comes as a surprise since these LAEs are identified as galaxies and their Lyα emission essentially can be ascribed to star formation, a process not included in our emission models, but currently thought to be dominant in the Lyα emission. How is that possible and why are the sources predicted by the simulations not seen in current surveys?

Furlanetto et al. (2005) and Faucher-Giguère et al. (2010) have addressed these issues at $z \sim 3$. Here, we compare the luminosity distribution of the bright sources identified from our simulation with the only existing LAE survey at similarly low redshifts, the GALEX spectroscopic surveys at $0.20 < z < 0.35$ (FUV) and $0.65 < z < 1.25$ (UV) (Martin et al. 2005). The GALEX surveys have found the LAEs to be less common and less luminous at the present time than at $z > 3$ (Deharveng et al. 2008; Cowie et al. 2010). Cowie et al. (2011) have shown recently that most of this evolution occurs over the $z = 0$ - 1 range. Since the luminosity distribution of the sources depends more strongly on the self shielding correction (see also Yang et al. (2008)) than on the redshift, we limit ourselves to the case of a single redshift, $z=0.35$, for which the

Note however that Lyα emission from star formation is included in their analysis.
Observable Signatures of the low-z Circum-Galactic and Inter-Galactic Medium : UV Line Emission in Simulations

Figure 11. Example of a compact bright Ly$\alpha$ source at z=0.75 with a simple spatial profile (one single core; center of image), as seen in a cube with a spatial resolution of 3 arcseconds. The image is a 40 by 40 pixel cutout, collapsed along the source’s maximum extent in z direction. At this redshift, this translates to 800 (physical) kpc. The green contours delineate areas of +0.5 dex in brightness. Note how all three bright sources in this image are clearly separated, and are up to 4 orders of magnitude brighter than their surrounding areas. The unit of brightness here is LU rather than CU as we have collapsed along the spectral axis.

luminosity function of LAEs is less uncertain than at 0.75 (Cowie et al. 2011). At a Ly$\alpha$ luminosity of about $3 \times 10^{41}$ ergs s$^{-1}$, the lower limit for the LAE luminosity functions, the density of Duchamp sources (cut 7) is found to be 23 times larger than the LAE density of $3 \times 10^{-4}$ Mpc$^{-3}$ ($\Delta \log L=1$)$^{-1}$ (Cowie et al. 2010). At a Ly$\alpha$ luminosity of $\sim 10^{42}$ ergs s$^{-1}$, the excess factor decreases to 2 (for cut 7, but is as large as 100 for cut 8).

There are however several reasons for missing objects like our simulated sources with the slitless GALEX spectroscopic survey. First, a number of the sources from the simulation may not be associated to any continuum stellar light, whereas the extraction of GALEX spectra is based on the existence of a dispersed continuum. Second, in slitless spectroscopy line emission is smeared in the dispersion direction by the angular extent of the object. For a typical bright source size of 100 kpc (i.e. 20 arcsec at z = 0.35) the Ly$\alpha$ FWHM would be increased from 7 Å (spectral resolution) to about 20 Å, resulting in a loss of contrast over the continuum and, at low signal to noise ratio, a non-identification as LAE or even a misidentification as AGN (if bright enough). Additionally, there is dilution in a direction perpendicular to dispersion, resulting in a loss of flux through the extraction window of 6 arcsec height. Even given all the uncertainties, we do not consider resonant scattering to be able to affect significantly the Ly$\alpha$ photons from cooling radiation, in contrast to the situation with Ly$\alpha$ photons resulting from star formation inside galaxies, where large optical paths through neutral gas may result in large quenching factors (if encountering dust particles) as well as extended halos (e.g. Steidel et al. 2011). In

Note that a comparison for cut 8 is less meaningful, since the curve is already declining at this luminosity value as a result of the method of analysis.
Figure 12. Example of a compact bright Lyα source at z=0.75 with a more complex spatial profile. The image has the same dimensions as Figure 11. Between the numerous sources in this image, there are ‘bridges’ connecting the bright sources that can reach up to 1/10 of the peak emissivity.

Table 3. Properties of typical bright emission regions as detected with Duchamp, at the redshifts specified in the text (Lyα z=0.76, OVI z=1.1, CIV z=0.35).

| Transition | Number density $n$[#/(Mpc/h)$^3$] | Typical Maximum Surface brightness (median and range) | log $L_{\text{[erg/s]}}$ | Spatial extent in FWHM [kpc proper] | Velocity structure |
|------------|----------------------------------|------------------------------------------------------|--------------------------|------------------------------------|-------------------|
| Ly-α       | $38 \times 10^{-3}$              | $> 3 \times 10^4$ CU                                  | 41.8 (39..43.5) (lenient cuts) 40.9 (39..42.2) (harsh cuts) | majority : 50..150 kpc          | Single peak 60%, double peak 25% Multiple peaks : 5%, other : 10% Maximum extent for multiple peaks : 1300 km/s |
| CIV        | $25 \times 10^{-3}$              | $5 \times 10^3$ CU                                   | 38.5 (36..41) (cut independent) | 25..100 kpc                      | Single peak 45%, double peak 30% Multiple peaks : 13%, other : 12% Maximum extent for multiple peaks : 800 km/s |
| OVI        | $17.3 \times 10^{-3}$            | $1.5 \times 10^4$ CU                                 | 39.2 (37..42) (cut independent) | 25..100 kpc                      | Single peak 60%, double peak 30% Multiple peaks : 2%, other : 8% Maximum extent for multiple peaks : 1000 km/s |
summary, the characteristics of the existing GALEX slitless spectroscopic survey may be able to explain the non-detection of extra Lyα sources predicted by simulations.

The fact that star-forming particles are excluded from our simulations, combined with the angular extension of our Lyα Duchamp sources, suggest naturally an interpretation of these sources as CGM emission from Lyα cooling radiation. This process has been repeatedly suggested to account for extended Lyα emission (e.g. Haiman et al. 2000; Fardal et al. 2001; Dijkstra et al. 2006; Dijkstra & Loeb 2009), especially in the context of the so-called Lyα blobs (e.g. Steidel et al. 2000; Matsuda et al. 2004; Saito et al. 2009), defined by an equivalent width \( W_{\text{Ly} \alpha} \geq 120 \) Å.

This interpretation would be consistent with our predictions of a larger density of sources with respect to that of LAEs, since LAEs are themselves a small fraction of the star-forming galaxies (5 percent at \( z \sim 0.3 \), Cowie et al. 2010), 25 percent at \( z \sim 3 \), Shapley et al. 2003, for LAEs defined by an equivalent width \( W_{\text{Ly} \alpha} > 20 \) Å.

The importance of Lyα cooling radiation has been challenged, however, by recent simulations (Zheng et al. 2011) and observations (Steidel et al. 2011), showing that spatially extended Lyα emission is a generic feature of high-redshift star-forming galaxies, resulting from Lyα photons initially produced by star formation and resonantly scattered by neutral atoms in the circumgalactic medium. Because of surface brightness threshold effects, the extended emission would hence be observed individually only in a limited number of cases. This would lead to an underestimation of the total Lyα flux by an average factor of 5 (Steidel et al. 2011). Such a factor, if applied to the luminosities of GALEX LAEs at \( z \sim 0.3 \), would be enough to make the resulting Lyα luminosity function dominant over the luminosity distribution predicted from Lyα cooling, at least for the cut 7 scenario (Fig. 11). In conclusion, this comparison validates our interpretation of the Lyα bright sources extracted from our simulations as CGM emission, but leaves the contribution of cooling radiation to the total Lyα emission observed within the uncertainties of simulations, and therein especially of the self-shielding corrections (Faucher-Giguère et al. 2010).

5 EXTENDED SOURCES/WHIM

This section gives a rough overview and some example plots for the structures that can be classified as 'filaments', i.e. here we take a look at the photons coming from regions outside the areas dubbed 'bright objects'. The main purpose is to be illustrative rather than quantitative and detailed, although some general features are summarised.

The procedure to produce the graphs below is to use the cubes resampled to FIREBall resolution (as described in 2.3), the specific cut values imposed are not important for these structures, the units of the data displayed here are in \( \text{LU} = \text{photons/(sec} \times \text{cm}^2 \times \text{sr)} \), as we integrate over the wavelength coordinate. The colour scaling of the images are chosen such that areas identified by the 3D-source finder Duchamp as 'bright sources' appear as white, compact 'blobs'. The flux outside these sources represents only a tiny fraction of the total flux (depending on the specific cut used less than 5% in the best case for Lyα, and even less in the metal lines). In addition, much of the remaining flux when flagging out the pixels identified as belonging to compact sources, is contained in areas very close to the volumes cut out (i.e. \( < 50 \text{ kpc vicinity} \)). Note that the contrast in flux density between the filaments and the bright blobs is up to 4 orders of magnitude, whereas there is another factor of \( \sim 50 \) in the surface brightness delineating the filamentary structures from the overall 'average' emission level.

Fig. 11 shows a typical situation for Lyα emission, as viewed by an instrument with roughly the specifics of FIREBall in angular and spectral resolution, but a much larger FOV (extended to \( 900 \times 900 \text{ arcsec}^2 \)). The filamentary structure connecting the bright sources has an extent in the x-y plane perpendicular to the line of sight of about 7200 kpc (physical), and extends over 6500 kpc in the z direction, assuming that velocity differences are not the main cause of the stretching over a wavelength range of 4.75 Å. Naturally, the boundaries of such structures are less well defined as the ones of the bright, isolated sources, so here we adopt the arbitrary definition whereby the outermost limit corresponds to the contour of the flux level 10 times higher than the median flux of all pixels. Then, the width of the long bridge, as measured perpendicular to the main direction between the bright sources, varies between 500 and 750 kpc. This rough 10:1 ratio of length to width is quite representative of the filamentary structures in Lyα.

An estimate by eye yields about 180 of such filaments in a cube of \( 25 \times \text{FIREBall FOV} \), corresponding to a length per volume of \( 2.5 \times 10^{-3} \text{ (Mpc/h)}^{-2} \), and a volume filling fraction of 0.1%. It is interesting to compare these estimates with the values of (Bond et al. 2010), who find and define filaments in their simulations via an algorithm that uses the eigenvectors of the Hessian matrix of the smoothed galaxy distribution. While their length measurements are of very similar size compared to ours (depending on the smoothing lengths they find \( l/V = 1.9 \times 10^{-3} \text{ or } 7.6 \times 10^{-4} \text{ (Mpc/h)}^{-2} \)), their filling factors (combining this length estimate with their mean filament widths) are of the order of 5%. This suggests that we are tracing similar structures (i.e. 'bridges' from and to massive and bright nodes of the Cosmic Web), explaining the similarity in overall length, but our focus on the HI emission outside of bound structures presumably results in much thinner sheets, as we are forced towards the densest parts of the gas. Following the definition above, the outermost regions of the filaments reach a surface brightness of about 0.1 IU, and even inside the filaments it usually remains below 5 IU, although very rarely bright spots (cf. the red-white areas of Figure 14) can obtain up to 50 CUs. This is still a factor of at least 5 below the lowest brightness for the bright sources, but at least 3 orders of magnitude brighter than the median flux density of the whole cube. Typical physical conditions of the gas encountered inside such filaments are roughly as follows: the density ranges from \( n = 5 \text{ to } 50 \times 10^{-6} \text{ cm}^{-3} \), whereas the temperatures are between \( 50,000 \text{ K} \leq T \leq 120,000 \text{ K} \).

Similar filaments can be seen in the metal line transitions OVI and CIV. These still consist of 'bridges'...
Figure 13. Examples of the 4 different classes of velocity profiles, here for the OVI emission. Note that the resolution of the representation chosen here (after resampling to the FIREBall specifics) is about 80 km/s per pixel. The coloured insets show the spatial images collapsed along the z axis as in Figure 11. The velocity plots are derived by collapsing the area shown in green along the other two axes, and translating the differences in the z direction to velocities (for details see text). The upper left panel shows a single peak in the spatial image, but the z-direction yields a profile that can be fitted well by a single Gaussian. The panel on the upper right is an example of a similarly simply spatially structured source, but with a double peaked velocity profile. The lower left panel exhibits again a single peak in x-y, but this time a much more complex, multiply peaked velocity profile. The lower right panel, finally, has a complex spatial structure, in combination with a multiply peaked velocity profile. Note the slight change in scale for the velocity plot for this example. Both the CIV as well as the Lyα compact sources show velocity profiles very similar to the ones depicted here, but the interpretation for the Lyα emission is complicated by a variety of factors (see text for details).

6 OBSERVING STRATEGIES

The idea of observing the emission from the IGM may be traced back to the early investigations of the nature of the UV (non-ionizing) background (e.g. Davidsen et al. 1974; Paresce & Jakobsen 1980) and the idea that the resonance lines of HI and HeII from the IGM may contribute to this background. The role of clumping was already recognized as primordial for the possibility of detection (Paresce et al. 1981). Since then, the association between the IGM emission and the UV domain has come to the forefront with the predictions of the WHIM and the CGM (Cen & Ostriker 1999; Davé et al. 2001). The development of this phase is expected to be maximum at low redshift and its temperature implies observations only through Lyα and high ionization species (OVI, CIV, etc) at UV rest-frame wavelengths. Except for the Lyα fluorescence observations which make sense at high redshifts and can be attempted from the ground (Rauch et al. 2008; Cantalupo et al. 2005), the
Figure 14. Example of a typical filamentary structure seen in Ly$\alpha$ emission at $z=0.75$. The size of the field in x and y is 900 x 900 arcsec$^2$, representing 6500 x 6500 kpc$^2$ (physical) at this redshift. The slice seen here has a thickness of 5.0 ˚A, corresponding to about 6700 kpc in z direction. The bright, compact sources, which exhibit peak surface brightnesses of more than 4 orders of magnitude brighter than the filamentary structures connecting them, appear as white 'blobs' in the colour scheme chosen here. Note that the flux seen in the filaments is not spread uniformly, but strongly concentrated towards these bright sources, exhibiting a bright circum-galactic medium around these, before trailing off into 'bridges' forming the familiar sight of the Cosmic Web. Note that for Ly$\alpha$ an additional contribution to the surface brightness may arise from the resonant scattering of Lyman line photons (a.k.a as 'photon pumping', see text for details.), which is not included in this representation here. The physical conditions prevailing for the gas forming these large bridges are as follows: density $n=5$ to $50 \times 10^{-6}$ cm$^{-3}$, temperatures in the range of $\sim 50,000 \leq T \leq \sim 120,000$ K.

WHIM and CGM-oriented observations have therefore to rely upon space or balloon experiments in the UV domain.

6.1 Detectability of bright, compact sources

What are the prospects of detecting the compact, bright sources identified via Duchamp as detailed in section 4.2. with current technology? And what may be the best instrumental approach set out for this task? Trying to gauge the detectability in a first approach, we have translated the Duchamp results into signal-to-noise-ratios (S/N) for each source, based upon the following simplifying, yet conservative assumptions. Note that certain aspects of the source detection already rely upon some fairly general instrumental characteristics (i.e. spatial and spectral resolutions). Furthermore, we assume to be dominated by the (cosmic) background as a noise source, and take this to be at a uniform level of about 500 CU (Brown et al. 2004; Morrissey et al. 2003; Murthy et al. 2010). For an effective telescope area of 230 cm$^2$ (representative of a meter-class space-based UV-experiment) and an exposure time of $1.0 \times 10^6$ s (representative of a typical deep exposure), we obtain the S/N ratios depicted in Figure 17 for the three different transitions at three different representative redshifts. The histograms have been computed from 3 emission-rich sightlines for each transition, totaling a combined ‘observed’ Field-of-View in each case of $3 \times 15 \times 15$ arcmin$^2$.

As can be easily seen, in this scenario we would be able to recover all of the Ly$\alpha$ emitting sources, regardless of the specific cuts (solid and dotted black lines) or redshift (black or cyan curves) with high confidence (the vertical green line indicates a S/N of 5.0). Hence, even uncertainties in the precise source position and its extent, will not jeopardise detection at all - note that we have implicitly assumed to know both quantities perfectly in this approach for our simulations (degrading this precision by e.g. including random areas classified by Duchamp as not belonging to the compact sources only marginally affects the S/N for any sensible number of additional pixels, as we have tested). Thus, for Ly$\alpha$, the two main problems to solve are: a. guaranteeing a large enough FOV to allow for enough detected sources (e.g. to perform meaningful statistical analyses), and b. finding suitable tracers to guide target selection from observables established as good proxies to emission from the simulation. The latter point is, of course, only relevant for instruments with multi-object spectrographs, as sources with S/N >5 will be detectable by blind searches with integral-field spectrographs.

The situation is somewhat different for the metal line transitions: both for the OVI and the CIV emitting regions, only a fraction of our simulated sources will be detected,
Figure 15. Example of a typical 'filamentary' structure in OVI at $z_{em}=1.1$. The size of the field is again 900 x 900 arcsec$^2$, translating to $7.4 \times 7.4$ Mpc$^2$. The depth (5 Å) represents 5.1 Mpc. Note the different scale in brightness as compared to Figure[14]: the filaments connecting the bright sources are now about three orders of magnitude fainter. The physical conditions of the gas forming the filamentary structures are very similar to the ones seen in Ly$\alpha$: the metallicity of such gas ranges from $10^{-3.5}$ up to $10^{-2.5}$, which is the main factor in those to be less bright. Note, however, that the flux is concentrated towards the bright sources even more than in the case for Ly$\alpha$.

regardless of the specific cut used for the self-shielding, which is largely unimportant for the brightness of these systems, as detailed earlier. As the blue and red histograms in Fig.[17]show, about half of the CIV (at a redshift of 0.37), and 2/3 of the OVI sources (at $z=1.1$) in our scenario may be missed. This fraction changes towards lower redshifts for OVI specifically, but note that the absolute number of sources per FOV then drops dramatically because of the enormously smaller area covered by the same opening angle (this effect can be seen e.g. in the two different redshifts for the Ly$\alpha$ sources). Hence, an additional complication for targeting metal lines emission areas compared to the search for Ly$\alpha$ sources is that one furthermore needs to be able to select tracers that guarantee to pick up the bright end of the distribution. Or be prepared to mostly rely upon stacking approaches because the majority of sources may individually lie below a detection limit, but collectively gather enough photons to statistically infer average quantities.

Under the given assumptions the S/N scales with $\sqrt{t_{exp} \times A_{eff}}$. Hence for different combinations of exposure time and telescope size, the distribution simply needs to be shifted horizontally by the appropriate factor. Furthermore, the absolute source number is a linear function of the FOV, and hence the distribution can be shifted up- and downwards depending on this quantity, rendering this graphical representation a versatile tool to judge mission goals.

A typical exposure time for a balloon-based experiment like e.g. FIREBall is about two orders of magnitude lower than indicated here - meaning that one can expect FIREBall to be successful in detecting Ly$\alpha$, and eventually a very small number of the brightest metal line emitting areas, depending on the size of the FOV. Note also, that in the case for Ly$\alpha$, we have specifically excluded photons stemming from star-forming regions, which may indeed be the major contribution to the flux, even at larger distances from the galaxies themselves due to the resonant nature of the Ly$\alpha$ transition (e.g. see Steidel et al. 2011 for examples at high $z$). While this additional contribution will facilitate detection of bright areas, it also complicates the analyses as the different components contributing to the total flux need to be separated.
Also note that we have thus far relied upon a fixed spectral coverage of only about 200 Å, comparable to the capabilities of FIREBall. Extending this coverage by almost a factor of 10, as planned for certain space-based missions, will not only vastly increase the survey volume and hence the number of detectable sources - in this context it is worth reminding ourselves that we do not find a significant evolution in the Lyα space density over the redshift intervals probed here, and thus the number counts should scale almost linearly with the survey volume - but also allow for the simultaneous observation of all three transitions, possible yielding important insights into the emitting material’s physical state.

6.2 Detection of filamentary structures

As expected, a quick glance at the PDF for Lyα emission (Figure 5 for Lyα at z=0.75, but also valid for all other redshifts) confirms that by far the largest fraction of the cosmic volume lies below any realistic chance of a direct detection, as the peak of the distribution reaches mere levels of $\sim 10^{-3}$ CU. Furthermore, a closer inspection of the flux remaining outside of the bright sources, which represent only 0.5 to 5% of the total flux to begin with, reveals that is not homogeneously distributed, but rather shows a complex spatial structure in our simulation, with isolated spots reaching up to 50 CU over volumes as small as 5 voxels.

We have conducted a few tests on a stacking approach. First, we have isolated by eye a few of the brighter filamentary structures such as seen for example in Figure 14 and added all their flux after removing the bright sources within them. Secondly, we have gone even one step further in our ‘naive’ idealisation, and simply combined voxels outside the bright sources in descending order of brightness regardless of their actual position, until we maximised the S/N for the combined flux in that fashion (note that there is a maximum number of voxels after which adding new cells in fact leads to a diminished S/N due to the additional voxel being so dominated by noise rather than signal). Both methods, applied to a mock observation with an exposure time of $10^6$ s and an effective telescope area of 230 cm$^2$, lead to marginal detections of the aggregated voxels, irrelevant of redshift and the specific cuts for self-shielded gas. Again, recognising that these two scenarios are extremely optimistic or even overly idealistic - in a real observation e.g. there is no a-priori information where exactly the filaments themselves or their brightest part are located - it is obvious that dec-
The distribution of the signal-to-noise ratios expected for the objects found in the data cubes, as detailed in the text and shown in Figure 9. Here we are assuming an exposure time of $10^6$ seconds, and an effective collecting area for an instrument of 230 cm$^2$, typical for a proposed deep field observation in future space-based missions. The noise is assumed to be a combination of photon noise and the extra-galactic background, which we take as 500 CU. Note that the absolute number of objects is a function of the FOV and the spectral coverage. The latter has been chosen to be representative of FIREBall, and may be raised by a factor of 5 or more for future space-based missions. The former is in this case, a $3 \times 15 \times 15$ arcmin$^2$ area of the sky. In addition to mass resolution effects (as is the main contributor for Ly$\alpha$), the shape of the distributions for the metals is also influenced by the imperfections of the source extraction algorithm, especially for OVI towards the low S/N end. For details, see the text.

Figure 17. The distribution of the signal-to-noise ratios expected for the objects found in the data cubes, as detailed in the text and shown in Figure 9. Here we are assuming an exposure time of $10^6$ seconds, and an effective collecting area for an instrument of 230 cm$^2$, typical for a proposed deep field observation in future space-based missions. The noise is assumed to be a combination of photon noise and the extra-galactic background, which we take as 500 CU. Note that the absolute number of objects is a function of the FOV and the spectral coverage. The latter has been chosen to be representative of FIREBall, and may be raised by a factor of 5 or more for future space-based missions. The former is in this case, a $3 \times 15 \times 15$ arcmin$^2$ area of the sky. In addition to mass resolution effects (as is the main contributor for Ly$\alpha$), the shape of the distributions for the metals is also influenced by the imperfections of the source extraction algorithm, especially for OVI towards the low S/N end. For details, see the text.

In reality, however, at least two aspects that may change this pessimistic outlook should be mentioned. First of all, as we have seen earlier, the mass resolution of the simulation may lead to an underestimate of the gas emission, specifically because it depends so non-linearly on temperature and densities. While this is most certainly the case for the brightest regions in the immediate vicinity of the densest and/or hottest areas, it seems less likely that large effects should be expected for the only slightly overdense and colder structures constituting the filaments, but we caution that even here clumping on scales smaller than resolved may occur.

Secondly, it is worth comparing the emission calculated with our simulation, based upon photo- and collisional ionization in an isotropic radiation field consisting purely of the average extra-galactic background, with estimates for at least one other process that we have identified already in 2.4 as not being incorporated properly into our modeling, i.e. the photon-pumping of local non ionizing continuum photons from galaxies. In order to calculate the potential additional emission at the order-of-magnitude level, we have devised the following toy-model at $z = 0.35$: we have assumed all filaments to be dust-free uniform cylinders illuminated by the UV continuum of young galaxies uniformly spread along their central lines. A 300 kpc proper FWHM diameter in HI has been taken, in rough agreement with the structures we have seen in paragraph 2.2. The cumulative comoving filament length per cubic megaparsec has been estimated by eye in one of our 900 $\times$ 900 arcsec$^2$ cones to be at $\sim 0.006$ Mpc$^{-2}$. In the present coarse approximation, effects due to filament inclination on the line of sight would induce changes at the few tens percent level and have been neglected. Those assumptions result in an average column density along a filament radius of $N_{HI} \sim 14.0$ cm$^{-2}$, able to}

14 As we have seen in paragraph 4 there are indeed filamentary structures in the metal lines very similar to the ones observed for Ly$\alpha$, yet due to the metallicity being much lower than unity, these are so faint that we can safely focus on the - as we have shown - already difficult to detect emission from hydrogen alone.
scatter 0.4 Å from a central continuum source when b = 30 km/s, independently of the velocity distribution in the gas. The total luminosity scattered by HI in the filaments has then been equal to the total energy absorbed along all lines of sight, with the central source's luminosity chosen to produce the same luminosity density near 1216 Å as measured by GALEX in the FUV (Schiminovich et al. 2005). We thus assume that most of the continuum near 1216 Å in a given portion of space is produced by flat continuum galaxies distributed in the filaments, a reasonable assumption at moderate redshifts where the UV flux is dominated by galaxies of small mass. We find the HI Ly-α luminosity density "pumped" under those assumptions to be 4 times above that from our simulation. The average filament surface brightness is found to be of the order of 10 LU, suggesting that areas with surface brightness in the hundred LU might not be uncommon given the luminosity spread of the illuminating galaxies in the real world, and the presence of clustering as already pointed out by e.g. Kollmeier et al. (2010). This coarse computation brings the emission from such a filamentary structure into the realm of achievable sensitivities for a space-mission, provided the FOV is large enough to cover a significant area. Keeping in mind that velocity information may not be as crucial (or interesting) for this gas (cf. e.g. figure 13 that shows the filaments not being spread over more than 100 to 200 km/s in velocity space), and also that high-spatial resolution is not mandatory, leaves us with the possibility of relaxing some of the instrument characteristics in order to maximise the S/N to be expected from the extended, faint emission regions.

We caution, however, that while such an additional contribution to the Lyα radiation can boost the chances of observability, it will tell us little about the physical state of the gas other than the distribution of neutral hydrogen and its velocity field (in conjunction with information about the non-ionising UV flux emanating from galaxies). The latter information though is relevant to the infall of cold gas.

7 SUMMARY

Exploiting a state-of-the-art large-scale AMR structure simulation, we examine the possibility of observing UV line emission at redshifts 0.3 ≤ z ≤ 1.2, focusing on the Lyα and two metal line transitions (OVI and CIV). The emissivity estimates for the gas in the simulation utilises the spectral synthesis code CLOUDY, adopting options most suitable for the treatment of the situation at hand (i.e. assuming a Haardt & Madau (2001) UV background with a zero percent escape fraction from galaxies as incident background at the simulation redshift; turning off the line pumping for all transitions). Being interested in the emission from extra- and circumgalactic gas, we exclude all photons coming from cells in the simulation that are starforming. Furthermore, we are bracketing the emission of self-shielding gas by setting it either radially to zero emissivity, or by assuming collisional ionisation equilibrium at the temperature and density provided by the simulation.

Generally speaking, we encounter two types of emission regions: relatively compact, bright, isolated objects, and large, faint filamentary structures permeating all of the volume, connecting such dense knots. The former represent (presumably) circumgalactic material that is of high enough density and temperature in order to emit at surface brightnesses that can easily be reached with current instrumentation, while the latter will certainly remain challenging even for future satellite missions, as detailed below. By degrading the AMR simulation to the spatial and spectral resolution of FIREBall, an instrument with characteristics very typical for UV balloon observations, we can assess realistically the chances of observing the gas, and furthermore can describe in detail which physical characteristics may be extracted from such observations.

Applying Duchamp, a standard source extractor algorithm, to the observationally-minded datacubes, we are able to isolate the bright, compact objects for all three transitions at the three different redshifts dictated by the FIREBall spectral window (1990 - 2260 Å, resulting in 0.64 < zcen < 0.84 for Lyα, 0.93 < zcen < 1.19 for OVI, and 0.28 < zcen < 0.46 for CIV). While extending over less than 0.1% of the cubes’ volumes, these bright sources carry more than 95% of the flux, even for the least optimistic assumption for the treatment of the self-shielding gas. The number density for the Lyman α bright sources in our simulation is η(Lyα, z = 0.8) = 3.8 × 10^{-3} (Mpc/h)^{-3}, whereas the densities for bright sources in CIV and OVI are η(CIV, z = 0.37) = 2.48 × 10^{-3} (Mpc/h)^{-3}, and η(OVI, z = 1.1) = 17.3 × 10^{-3} (Mpc/h)^{-3}. While for the brightest areas in Lyα the range depending on the specifics of the self-shielding treatment can be up to two orders of magnitude, the effect for the metal lines is minimal, as the main contribution to the light emitted stems in their cases from gas of temperatures well above any of the self-shielding cuts. Hence, our estimate for the median luminosity for the Lyα sources ranges from log L [erg/s] = 40.9 to log L = 41.8, while the median luminosities for the metal lines are robust against changes in the treatment of self-shielding: log L (OVI) = 39.2, and log L (CIV) = 38.5. Keep in mind, however, that while the luminosity distribution for Lyα sources peaks sharply roughly at its median value, the distributions in OVI and CIV are much broader, without a clearly preferred peak. The overwhelming majority of all sources, Lyα and metal lines, extend over roughly spherically symmetrical areas between 50 to 100 kpc (proper FWHM (when fitting images collapsed along the velocity component)/z direction of the cubes by 2D Gaussians), but in a few percent of the cases, the source can obtain sizes of up to 300 kpc. The morphologies of such large sources are often more complex, hinting at their being several, individually unresolved smaller ones in a group or cluster. Interpreting the sources’ profile along the z axis of the cube as a velocity profile, we encounter a variety of different cases: on the order of 60% of the objects (again in all three transitions) exhibit a single peak, with a median FWHM of 215 km/s, and a range from 150 < σ < 400 km/s. Next, there is

15 The number of sources, however, is strongly dependent on the simulation resolution. See the Appendix for details regarding convergence.
a large group of sources (~25% of the cases) which show a double peaked profile, roughly split in half by ones that are symmetrical and others where one peak clearly dominates. Interestingly, for this group of objects with double-peaked velocity profiles their spatial profile looks in almost all cases still indicative of one single source, which is not true for the last group of objects with more complex, multiply peaked velocity structures. While some of the members of this category can have relatively simple spatial structure, many of them are clearly examples of multiple, yet unresolved individual sources within the window over which we extract the velocity information. In general, the velocity spread over the whole source is less than ±400 km/s from the brightest pixel, but in rare cases can span almost 1300 km/s.

In contrast to these bright, isolated sources with sharp 'edges', the morphology of the filamentary structures connecting the nodes of the Cosmic Web are more complex with much less well defined boundaries. For all possible scenarios dealing with the self-shielding cuts, they collectively carry less than 5% of the flux in Lyα, and even less in the metal lines. Adopting a straight-forward definition to delineate these from the surrounding medium (outermost contour has to have a surface brightness 10 times larger than the median flux of the whole cube), we extract filaments that exhibit roughly a 10:1 ratio of width to length. The width, defined as length perpendicular to the longest segment connecting bright nodes, of these structures are between 500 and 750 kpc (physical). Within the definition above, the boundaries for the Lyα filaments occur roughly at 0.1 CU, and remain inside those usually below 5 CU, although rare bright spots may obtain up to 50 CU. The brightness of filaments in the metal transitions is about 2 orders of magnitude below that of Lyα, largely an effect of the metallicity inside the filaments being of that order of magnitude below solar. Typical physical conditions of the gas encountered inside such filaments are roughly as follows: density ranges from $n = 5 \times 10^6$ cm$^{-3}$, temperatures are between $T = 50000 \lesssim T \lesssim 120000$K, and gas metallicity tends to be slightly below $10^{-3}$ of the solar value, but can reach up to $10^{-2}$ in a few, isolated spots, usually near the bright sources. The flux distribution inside the filaments is not at all homogeneous, with about 50% of it stemming from areas in the close vicinity of the bright sources ($\lesssim 50$ kpc). Given all these characteristics of the filamentary structures it is clear that their detection will remain a challenging task for the near future.

Applying simplifying and conservative assumptions about source extraction as well as background and detector noise, we conclude that the bright sources in Lyα associated with the CGM will easily be picked up with high confidence by instrumentation with current (or soon to be deployed) technology. For example, all of the simulated Lyα sources at $z=0.76$, and a large fraction of the metal line transitions OVI and CIV exhibit S/N ratios in excess of 10 when ’observed’ by a meter-class space-based UV telescope with an effective area of 230 cm$^2$ in a moderately long exposure of $10^6$ seconds. While a balloon-based experiment with shorter duration observations will also be able to retrieve the majority of the Lyα objects, the fraction of objects bright enough in the metal lines drops to the few percent level. A spatial resolution of 3-5 arcseconds suffices to minimally resolve the bright CGM areas extending up to 200 kpc, and is currently easily obtainable technologically. Furthermore, a spectral resolution of ~0.5 Å allows to extract the velocity profiles of these objects, and hence obtain kinematic information on the light-emitting gas distribution. The space density of the bright sources is high enough that even with a relatively short spectral coverage of ~200 Å, already feasible with current detectors and dwarfed by possible space-based instruments that are poised to cover much more of the UV, surface densities can be achieved that guarantee sufficient numbers of objects in a survey field of a few arcmin$^2$, such that meaningful population analyses can be performed. Given these scenarios, the next question to be addressed has to be how to select good tracers in a possible surveying campaign. Note that we have purposefully neglected all stellar light emanating from the galaxies themselves, or even scattered Lyα radiation, and hence our surface brightness estimates are strictly lower limits. In fact, distentangling such different components from the radiation we have simulated in our approach will become an important caveat for any survey. Hence, simply choosing UV-bright galaxies as targets may not be the best way forward. Other source characteristics (e.g. metallicity, or environment) may serve better, and we are currently investigating this question.

ACKNOWLEDGMENTS

This work has been funded within the BINGO! (’history of Baryons: Ntergalactic medium/Galaxies eO-evolution’) project by the Agence Nationale de la Recherche (ANR) under the allocation ANR-08-BLAN-0316-01. Access to the HPC resources of CINES was granted and funded under the allocation 2010-x2010042191 made by GENCI (Grand Equipement National de Calcul Intensif).

APPENDIX : CONVERGENCE TESTS

Especially towards areas of high density and/or temperature, the ability to resolve small enough scales to capture...
many of the relevant processes at least to some detail is crucial. As pointed out in the main text, e.g.
the number of the bright sources is a strong function of the simulation (mass and spatial) resolution. A variety of tests can be performed in order to assess whether a simulation has converged onto stable values in a wide range of parameter space. Because we are mainly interested here in the light emission of the gas outside starforming particles, we focus in this Appendix on two aspects regarding the bright, compact sources, and the surface brightness of all voxels outside these.

Fig. 18 shows the luminosity distribution of bright sources in \( \text{Ly} \alpha \) isolated in exactly the same manner for two simulations with different resolution. Both simulations are examined at the same redshift (\( z=0.75 \)), and over exactly the same volume. Whereas the black histogram shows the luminosities of detected sources in the original high resolution simulation, when applying the most lenient approach for handling the self-shielding, the red curve depicts sources found in a simulation that was run with half the resolution in each spatial direction, and hence with a mass resolution of a factor of 8 less. Clearly, the number of such bright sources is a strong function of the resolution: there are about 5 times as many such bright sources in the high resolution simulation. However, it is also obvious that almost all of the 'new' sources (as compared to the lower resolution output) are of lower luminosity, and their combined emission does not add substantial light to the total \( \text{Ly} \alpha \) radiation, which is dominated by the most luminous sources. Above an approximate limit of \( \log L (\text{Ly} \alpha) \sim 41.6 \) both curves start to match. Hence, we conclude that the simulation has converged down to that limit of luminosity. In this sense, the number densities for the bright sources are strictly only lower limits.

Outside of the bright sources, however, the situation is different. Fig. 19 shows the surface brightness distributions of the same two simulation outputs mentioned above, after in each one the voxels identified to be belonging to bright compact sources (and a cushion of 5 pixels around these) have been removed. Those two histograms are remarkably similar, with only a very tiny minority of areas exhibiting a slightly brighter flux in the high-resolution cube. In that regard, we are able to assess that for the mildly over- to underdense regions singled out by cutting out the bright sources the simulation, not very surprisingly, has converged, rendering the predictions for those areas stable.

Note that for both metal lines similar arguments hold.

This paper has been typeset from a \TeX/ \LaTeX file prepared by the author.
Figure 18. The luminosity distribution of the bright Lyα sources at z=0.75 extracted with the same source finding parameters in two cubes of the same volume with different spatial and mass resolutions. The black curve shows the results obtained in the simulation used throughout the paper, whereas the red histogram is derived from a simulation with a spatial resolution of a factor of 2 lower (in each dimension), and hence a mass resolution of a factor 8 worse. Note the strong dependence of the number of sources on the resolution: increasing the resolution in this fashion leads to about 5 times more sources in the same volume. The majority of the new sources, however, are much less luminous, and hence their contribution to the total light is small. The two curves start matching around log L $\sim$ 41.6, and hence we conclude that down to this luminosity the simulation has converged.
Figure 19. The surface brightness distributions of two Lyα cubes at z=0.75 after removing the bright sources. The black curve shows the results obtained in the simulation used throughout the paper, whereas the red histogram is derived from a simulation with a spatial and mass resolution of a factor 8 worse, as in Fig. 18. Unlike for the bright sources, there is little difference in the two histograms, indicating - as expected - that for areas of moderate overdensity the simulation has reached convergence. There is a small number of pixels inside filamentary structures that exhibit surface brightnesses of about half a dex higher in the higher resolution cube, but those are so rare and spread out over wide volumes that they do not contribute significantly to the brightness of one specific filament.
