Risk indices

A B S T R A C T

Polycyclic Aromatic Hydrocarbons (PAHs) levels in four commonly consumed smoked fish species from markets in Southern Nigeria were assessed to evaluate possible human health risks associated with consumption. Varying levels of PAH congeners were observed in the fish tissues with the highest total concentration of PAHs in Scomber scombrus. High concentrations of benzo(a)pyrene were observed in Clarias gariepinus and Ethmalosa fimbriata with values above the guideline value of 0.05 mg/kg. The Dietary Daily Intake (DDI) value for total PAHs (ΣPAHs) was highest for S. scombrus while the DDI value for the total carcinogenic PAHs (ΣCPAHs) was highest for E. fimbriata. Carcinogenic human health risk assessment using carcinogenic toxic equivalents (TEQ), indicated that consumption of E. fimbriata has a higher potential to cause carcinogenic risks. TEQ values for all the fish species were however, below the estimated screening value (SV) of 3.556 mg/kg, while the estimated cumulative excess cancer risk (ECR) for E. fimbriata and C. gariepinus and PAH4 index for all the assessed fish species exceeded threshold values indicating potential carcinogenic risk from consumption.

1. Introduction

Polycyclic aromatic hydrocarbons (PAHs) are an important group of compounds of major environmental concern. There are several possible sources of PAHs in the environment, anthropogenic activities are, however, considered major sources of PAHs in the environment. Among the anthropogenic sources, petrogenic and pyrolytic sources are considered to be the most important. More than 100 PAHs have been characterized, 16 of which were classified by United States Environmental Protection Agency (USEPA) as priority pollutants because of their toxicity [1]. PAHs has been reported to be highly mutagenic and carcinogenic in humans [2].

Dietary exposures are the major source of human exposure to PAHs [3]. PAHs are found in food as a result of food processing techniques like curing, drying, smoking, roasting, grilling, barbecueing and refining. These food processing steps are known to generate and increase the level of PAHs in the food [4]. One significant food source of PAHs is smoked fish [5]. In developing countries, smoked fish is a common source of protein in most diets, smoke not only gives the fish special taste and aroma, it also improves preservation due to its dehydrating and bactericidal properties [5,6]. However, smoke especially wood smoke contains PAHs, many of which are carcinogenic [3]. In developing countries, smoking is the most common method employed in preserving fish. In Nigeria, smoked fish products constitute about 61% of the total 194,000 m t of dry fish produced [6]. Smoked fish products are the most available form of fish product for consumption [6], which could be attributed to the fact that most of the fishing communities have limited access to electricity to preserve their fish products [6]. This has however increased the risk of PAHs contamination through consumption. Food Safety is of growing concern globally and PAHs residues if present in smoked fish above recommended levels could pose serious public health concerns [7]. Previous studies have shown the presence of PAHs in smoked fish [3,8,5,6], however, studies on human health risk associated with consuming smoked fish are rather scanty [9], especially for reported studies from Nigeria.

The objective of this study was, therefore, to determine the concentration of PAHs in four locally available and commonly consumed smoked fish species (Clarias gariepinus, Ethmalosa fimbriata, Tilapia zilli, and Scomber scombrus) from markets in Southern, Nigeria, in order to assess possible human health risks associated with consumption.

2. Materials and methods

2.1. Sample collection

Samples of Clarias gariepinus, Tilapia zillii, Ethmalosa fimbriata, and Scinorobenus minor, were randomly collected from three major markets (Oreogbeni (6° 21' 0.09" N and 5° 29' 32.67" E), New Benin (6° 23' 59.96" N and 5° 36' 67.37" E) and Santana market (6° 17' 44.66" N and 5° 38' 8.99" E) in Southern Nigeria (Fig. 1).

The selected markets are major sources of smoked fish for most markets in Southern Nigeria. Samples were wrapped in aluminum foil, packed in labeled polythene bags and transported to the laboratory for analysis. Samples were collected every month for four months (June–September).

2.2. Extraction and analysis

Extraction of PAHs was carried out based on the method described by [10]. 10 g of the homogenized fish sample was thoroughly mixed with anhydrous Na$_2$SO$_4$ to dehydrate the sample. 20 ml of the extraction solvent (di-chloromethane) was added to the sample. Samples were covered with aluminum foil to prevent evaporation and sonicated to separate supernatants of extracts. Extracts were concentrated using an evaporator. Extracts were then cleaned up using a chromatographic column, moderately packed at the bottom with 1 cm glass wool. 2 g of silica gel and 1 cm of anhydrous Na$_2$SO$_4$ was added to the column while the column was pre-eluted with 20 ml dichloromethane. Extracts were then concentrated and collected in 2 ml vials.

2.2.1. Chromatographic analysis

The cleaned up extracts were analysed for naphthalene, acenaphthylene, benzo[b]fluoranthene, phenanthrene, dibenz[a,]anthracene, chrysene, benzo[a]pyrene, acenaphthene, benzo[k]fluoranthene, fluorene, pyrene, benzo[a]anthracene, anthracene, fluoranthene, indeno[1,2,3-cd]pyrene, and benzo[g,h,i]perylene. Corresponding results were obtained using Gas chromatography (GC, Hewlett-Packard HP-5890 Series II with flame ionization detection (GC-FID)). The GC was programmed as follows: initial temperature of 60 °C for 2 min and ramped at 25 °C/min to 300 °C for 5 min and allowed to stay for 15 min giving a total run time of 22 mins. A 2 μl volume splitless injection mode was used and the injection port temperature was set at 250 °C, while 300 °C was maintained for the injection port of the FID detector. A standard mixture of 17 priority PAHs (Naphthalene, Acenaphthylene, Acenaphthene, Fluorene, Phenanthrene, Anthracene, Fluoranthene, Pyrene, Benzo[a]anthracene, Chrysene, Benzo[k]fluoranthene, Benzo[a]pyrene, Benzo[b]fluoranthene, Indeno[1,2,3-cd]pyrene, Dibenzo[a,h]anthracene and Benzo[g,h,i]perylene) was obtained and used for the analysis. Compounds were identified by comparing the retention time of standards with that obtained from the extracts and individual analysis of PAHs were used for quantitation.

Naphthalene, Acenaphthylene, Acenaphthene, Fluorene, Phenanthrene, Anthracene, Fluoranthene, Pyrene were the assessed non-carcinogenic PAHs, while Benzo[a]anthracene, Chrysene, Benzo[k]fluoranthene, Benzo[a]pyrene, Benzo[b]fluoranthene, Indeno[1,2,3-cd]pyrene, Dibenzo[a,h]anthracene and Benzo[g,h,i]perylene were the assessed carcinogenic PAHs [1].

2.3. Human health risk estimations

2.3.1. Regulatory limits and guidelines

The toxicological risk associated with PAH concentrations in smoked fish was assessed through comparison of the observed concentrations with regulatory limits and guidelines. Concentration of PAHs in the smoked fish species were assessed for individual PAH concentrations, total PAH concentrations (sum of all the assessed PAH congeners) and total carcinogenic PAHs (sum of the carcinogenic PAHs [1], namely Benzo[a]anthracene, Chrysene, Benzo[k]fluoranthene, Benzo[a]pyrene, Benzo[b]fluoranthene, Indeno[1,2,3-cd]pyrene, Dibenzo[a,h]anthracene). Concentrations of Benzo[a]pyrene (B[a]P), which has been accepted as a marker for the occurrence and effect of carcinogenic PAHs in smoked foods as specified in the European Commission Regulation(EC) No 1881/2006, was compared with the maximum acceptable level of 0.005 mg/kg [11] for benzo[a]pyrene in smoked fish.

2.3.2. Potential human health risk from consumption of smoked fish

To assess human health risks from exposure to PAHs through consumption of smoked fish (dietary intake), human intake models were applied. The Dietary Daily Intake (DDI) concentrations of PAHs from consumption of contaminated smoked fish species were assessed. Carcinogenic risks were also assessed by evaluating the carcinogenic potencies of individual PAH concentrations($B\,(A)\,P_{eq}$), the Carcinogenic toxic equivalents (TEQs) and the Excess Cancer Risk Index. Values used for parameterization of the human intake models is presented in Table 1.

2.3.2.1. The dietary daily intake (DDI).

The Dietary Daily Intake (DDI) of PAHs in the smoked fish species was assessed for adult population using Eq. (1) [18]. The daily intake of PAHs from smoked fish was evaluated by multiplying the respective PAH concentration in each fish sample by the fish ingestion rate (IFR) of an average weight adult (70 kg) from Nigeria. The consumption rate for fish in Nigeria for an average adult population was obtained from data of the Food Agriculture Organization (FAO) 2014 [19], on Fishery and aquaculture statistics. Evaluation of Dietary Daily Intake (DDI) was calculated for individual PAH congeners, the sum of the 16 PAHs analyzed (Total PAHs) and also for the sum of those PAHs considered possible human carcinogens (Total Carcinogenic PAHs).

The Dietary Daily Intake (DDI) = Ci × IFR

(1)

2.3.2.2. Carcinogenic risk assessment of PAHs in smoked fish.

Cancer risk due to dietary exposure to PAHs in smoked fish was assessed using the PAH4 index. Individual PAH carcinogenic potencies, the carcinogenic toxic equivalents (TEQs) and the excess cancer risk index.

The PAH4 index was assessed in this study based on the review by the Contaminants in the Food Chain (CONTAM) Panel, in 2008 relating to occurrence and toxicity of PAHs in food, which concluded that PAH4 is a more suitable indicators of PAHs in Food [20]. PAH4 was evaluated using Eq. (2), as the sum of four different polycyclic aromatic hydrocarbons, namely benzo[a]anthracene (B[a]A), chrysene (Chr), benzo[b]fluoranthene (B[b]FL), and benzo[a]pyrene (B[a]P). The estimated PAH4 index of each fish species was then compared with the maximum permissible level to determine the occurrence and effect of carcinogenic PAHs in the smoked fish samples. The maximum permissible level of 0.03 mg/kg for the sum of PAH4 in smoked fishery products as recommended by the European Union (EU) Commission Regulation, No 1327/2014 in 2014 [11], as regards maximum levels of polycyclic aromatic hydrocarbons (PAHs) in traditionally smoked fish and fishery products was applied.

PAH4 Index (PAH4) = \sum B[A]A + Chr + B[ b]FL + B[a]P

(2)

The Carcinogenic potencies of individual PAHs $B\,(A)\,P_{eq}$ was evaluated by multiplying the PAH concentration in the sample by the individual toxicity equivalency factor (TEF) (Eq. (3)) [12].
Carcinogenictoxicequivalents (TEQs) of individual PAH fractions are used to assess health risks of PAHs to humans from fish consumption. The carcinogenic potency of each PAH is expressed as a congeners to benzo(a)pyrene (B(a)P) potency (C). The TEFs developed by Nisbet and LaGoy [12] were applied to calculate TEQs for individual PAHs in smoked fish species.

The excess cancer risk induced by dietary exposure to PAHs via smoked fish consumption was assessed using Eq. (6) [23].

\[
\text{Excess Cancer Risk (ECR)} = \frac{\sum Q \times B(a)P_{eq} \times IFR \times ED}{(BW \times ATn)}
\]  

(6)

2.4. Statistical analysis

Data analysis were performed using Microsoft Excel 7.0 program. Multiple bar graphs were used for the pictorial description of assessment endpoints. Individual PAHs, Total PAHs (\(\sum_{PAHs}\)), and total carcinogenic PAHs (\(\sum_{CPAHs}\)) concentrations were summarized separately for each fish species using descriptive statistics (means, range, standard deviation, standard error). Statistical differences between individual PAH concentrations, low and high molecular weight PAHs, ring types, dietary daily intake (DDI), and carcinogenic potencies of individual PAH concentrations (B(a)P_{eq}), between the species were performed using Analysis of variance (ANOVA) at 0.05 level of significance.

3. Results and discussion

3.1. Concentration of PAHs in smoked fish

The mean concentrations of individual PAH congeners in the smoked fish species samples from the various markets in Southern Nigeria is presented in Table 2. The total concentrations (mg/kg)
Table 2
Mean concentration (mg/kg) of PAH on smoked fish species from markets in Southern, Nigeria.

** Carcinogenic PAHs.
*** Carcinogenic PAH and PAH used to derive the PAH4 Index.

of PAHs were 0.715, 0.951, 0.694, and 3.585 in C. gariepinus, T. zilli, E. fimbrata, and S. scombrus respectively. The high values of PAHs observed in the smoked fish samples might be attributed to the smoking process during preparation and preservation. The basic process of fish smoking in Nigeria is by heating the fish over partially burning wood. This process generates wood smoke which gives the fish special taste and aroma, however, most PAHs in smoked foods, especially fish, comes from wood smoke [8] and wood smoke has been reported to contain a large number of PAHs [24]. The total carcinogenic PAH concentrations (mg/kg) were 0.446, 0.222, 0.467, and 0.201 in C. gariepinus, T. zilli, E. fimbrata, and S. scombrus respectively (Table 2).

Total mean concentrations of PAHs was highest in S. scombrus (Table 2), with mean concentrations of individual PAHs ranging from 0 to 1.172 mg/kg. Similar results of higher concentrations were reported for S. scombrus by [25]; in a study of PAHs concentration in six species of smoked fish from in Western Nigeria. Mean concentrations (mg/kg) of PAH congeners in the other fish species ranged from 0 to 0.204 (C. gariepinus), 0–0.315 (T. zilli), and 0–0.288 (E. fimbrata). PAH concentrations between the fish species were significantly different (p < 0.05, F = 4.26). The differences observed in PAHs concentration between the species could be attributed to differences in fat and moisture compositions of each species alongside the nature of the skin cover [26]. Results from this study is similar to studies by Igwe et al. [25], Yusuf et al. [27] and Silva et al. [6], who reported varying concentrations of PAHs in different species of smoked fish in Nigeria. Total PAH in smoked fish species observed in this study was also compared with PAH in smoked fish observed from other parts of Nigeria [6,25,28,27] and other countries [29,30,35]. It was observed that concentrations in this study were above these reported concentrations. This may be attributed to the increased use of the traditional smoking method in the preparation and preservation of fish. Several studies have shown that smoking fish using traditional methods, increases the amount of PAH formed in smoked fishes [6,27]. Naphthalene was the most dominant congener in T. zilli, and S. scombrus, making up 33.3%, and 32.7% of the total PAH residues respectively (Table 2), while Benzo(b)fluoranthen was the most dominant congener in C. gariepinus and E. fimbrata comprising 28.5% and 41.5% respectively (Table 2).

The total carcinogenic PAH concentrations were highest in E. fimbrata (0.467 mg/kg), although concentrations were not significantly different (p > 0.05, F = 4.26) between the species. This high concentrations observed in these species may possibly be linked to the type of smoking process used during the preparation of this fish species. Pyrolysis of polycyclic aromatic hydrocarbon residues leads to the formation of additional higher molecular weight polycyclic aromatic hydrocarbons and, consequently increases the polycyclic aromatic hydrocarbon concentration in the samples [31]. E. fimbrata is usually prepared using an intense smoking process that involves the direct exposure to hot smoke from burning wood fire a process that takes place for about 2–5 days [32]. The high concentration of total carcinogenic PAHs in E. fimbrata is, therefore, a course for concern.

Benzo(a)pyrene concentrations were observed to be highest in C. gariepinus and E. fimbrata with mean concentrations of 0.10 and 0.13 mg/kg respectively. Observed concentrations were higher than the maximum acceptable level (0.005 mg/kg), for benzo[a]pyrene in smoked fish [33] which calls for serious health concern. Considerable attention has been drawn to B(a)P residues in foods because of its possible carcinogenicity to humans [34,35]. However, Benzo(a)pyrene concentrations were only observed in 6% of all the assessed smoked fish sample.

3.2. Human health risk assessment of PAH in smoked fish

3.2.1. Dietary daily intake (DDI) of PAH’s from consumption of smoked fish

In Nigeria, there is a high rate of consumption of fishes and smoked fish products are the most ready form of fish product for consumption [36]. Therefore, using the concept of DDI to assess the health risk of toxicants is imperative. The concept of DDI to assess health risks from toxicants is usually applied because of differences in fish consumption rates [37]. Table 3 summarizes the dietary daily intake (DDI) of PAH’s in the analysed smoked fish samples for an adult (70 kg) population in southern Nigeria. DDI values (mg/day) estimated from individual PAH concentrations in smoked fish ranged from 0 to 0.0112 (C. gariepinus), 0–0.0173 (T. zilli), 0–0.0158 (E. fimbrata), and 0–0.0642 (S. scombrus) (Table 3). Differences in DDI values between the fish species were statistically significant (p < 0.05, F = 4.26). The DDls (mg/day) of Benzo(a)pyrene, which is one of the most potent animal carcinogen were 0.005 and 0.007 for C. gariepinus and E. fimbrata respectively. Benzo(a)pyrene
was not detected in T. zilli and E. fimbriata. The DDI for E. fimbriata was again highest. The estimated DDI (mg/day) values for total PAHs ($\sum$PAHs) in the assessed smoked fish were 0.039, 0.052, 0.038, and 0.195 for C. gariepinus, T. zilli, E. fimbriata, and S. scombrus, respectively (Table 4), while the DDI (mg/kg) for the total carcinogenic PAHs were 0.025, 0.012, 0.026, and 0.011 for C. gariepinus, T. zilli, E. fimbriata, and S. scombrus, respectively (Table 4). The DDI value for total PAHs ($\sum$PAHs) was highest for S. scombrus while the DDI value for the total carcinogenic PAHs ($\sum$CPAHS) was highest for E. fimbriata. The results indicate that the consumption of S. scombrus in preference to the other fish species will result in higher risk of exposure to PAHs while the consumption of E. fimbriata will result in higher risk of exposure to carcinogenic PAHs.

A comparison with other studies showed that the observed DDI values for $\sum$CPAHS and $\sum$PAHs through the consumption of these fish species were higher than reported studies from Ghana [37] with DDI values of 201 ng/d and 7548 ng/d for $\sum$CPAHS and $\sum$PAHs respectively. DDI values for $\sum$PAHs in the fish species were also higher than reported studies from Spain with DDI values of 626–712 ng/d [38], India with DDI values of 1.77–10.7 ng/kg bw/day [39] and Kuwait with DDI values of 231 ng/d [40]. Higher DDI values observed in this study could be attributed to the relatively higher concentrations of PAHs in the smoked fish species assessed in this study.

The higher values obtained in this study may also be attributed to the higher use of the traditional method for processing and preserving these fish which might have invariably caused an increase in PAH concentrations in these fish species. Fish vendors in Nigeria usually re-smoke fish continuously until they are sold in the market in order to increase the shelf life of the fish [6], since preservation using electricity is usually not feasible. The DDI’s for individual PAH concentrations were also compared to the available reference dose [1] to determine long-term risk from exposure to PAHs residues through the consumption of smoked fish. The observed DDI values were however, generally below the reference dose for all the smoked fish species assessed.

3.2.2. Carcinogenic risk assessment of PAHs in smoked fish

The estimated PAH4, individual PAH carcinogenic potencies, carcinogenic toxic equivalents, screening value and excess cancer risk are presented in Tables 3 and 4.

### Table 3

| PAH | RID | TEF | Clara gariepinus | Tilapia zilli | Ethealosa fimbriata | Scomber scombrus |

**TEF** values for the PAHs was adopted from [12].
* Non-Carcinogenic PAHs.
* Carcinogenic PAHs.
** Carcinogenic PAH and PAH used to derive the PAH4 Index.
contains a large number of PAHs [8] whose formation is basically dependent on temperature. The temperature of smoke is important because the amount of PAHs formed during pyrolysis increases as the smoking temperature increases [2]. High-temperature smoking increases PAH concentrations to high levels and may contain a large variety of PAHs, including the most carcinogenic ones [2]. TEQ values reported in this study were higher than values reported by Yusuf et al., [27], for PAH in smoked fish from Western Nigeria, especially for Catfish. Furthermore, the observed TEQ values for the assesed smoked fish values were also higher than values reported by Iwegbue et al. [41] for C. gariepinus (0.06 mg/kg). E. fimbriata (0.0057 mg/kg) and S. scombrus (0.00258 mg/kg) collected from markets in Nigeria.

3.2.2.4. Screening value of PAHs in the smoked fish. The screening value (SV) was evaluated to assess the health risks of PAHs to humans from consuming these four fish species. This value is the threshold concentration of a chemical in edible tissues that is of potential public health concern [21, 22]. An estimated screening value (SV) of 3.556 mg/kg was obtained. Results showed that the TEQ values for all the fish species were below the SV of 3.556 mg/kg (Table 4). Results from this study, were not consistent with the report of Ikue et al. [43], in a study of PAH contaminants in Chrysichthys nigrodigitatus in Rivers State, Nigeria, who reported calculated TEQ values above estimated screening values, indicating potential health effects. Nozari et al. [44] also reported higher TEQ values when compared to calculated SV values for PAH in seafood (fish, crab, and bivalve) in Iran at a consumption rate of 55.1 g/d. However, results from this study agrees with reported studies of PAH concentrations in fish (fetal finfish) from Hong-Kong market [21], and PAHs in the common eel (Anguilla anguilla) from River Tiber, Italy [45] were the estimated TEQ values were lower than the SV.

3.2.2.5. Excess cancer risk and PAH4 index of PAHs in the smoked fish. The excess cancer risk (ECR) of an adult population with an average weight of 70 kg caused by dietary exposure to PAHs was evaluated. The estimated ECR resulting from lifetime exposure to PAHs through fish consumption were compared to the acceptable guideline value of 10⁻⁶ set by USEPA [46]. USEPA stipulates that a level of risk where there is a lifetime cancer risk of one in a million (ECR = 10⁻⁶) over a 70-year lifetime period, is considered acceptable, while an instance where there is an additional lifetime cancer risk of one in ten thousand or greater (ECR = 10⁻⁴), is considered serious [54].

In this study, the ECR values for all the assed PAH congeners in all the fish species were lower than the USEPA threshold value (10⁻⁶) (Table 3). However, cumulative excess cancer risk for E. fimbriata (0.00000591 mg/kg) and C. gariepinus (0.00000424 mg/kg) exceeded the USEPA's acceptable cancer risk level of 10⁻⁶ having higher cancer estimates than the other smoked fish species. This indicates that consumption of E. fimbriata and C. gariepinus in preference to the other species of fish could result in potential cancer risk.

Similar studies in India [39] and Ghana [37] have reported estimated excess cancer risk from consumption of fish above the USEPA guideline values. In addition, similar studies on excess cancer risk from consumption of other foods has also been reported above the guideline values [47, 48].

4. Conclusion

Priority polycyclic aromatic hydrocarbon (PAH) were detected in four species of smoked fish obtained from major markets in Southern Nigeria. Varying levels of PAH congeners were observed in the smoked fish species with the highest total concentration of PAH in S. scombrus. The high concentration of benzo(a)pyrene in C. gariepinus and E. fimbriata above the guideline value of 0.05 mg/kg calls for serious health concern. Furthermore, the observed values of PAH4 and the cumulative ECR for E. fimbriata and C. gariepinus above the recommended values is also a cause of worry. The study, therefore, deduces that there are substantial exposure and possible carcinogenic human health risk from consumption of smoked fish species from Southern Nigeria. Education of fish mongers and vendors on safer processing and preserving alternatives is imperative.
