A cryptic RNA-binding domain mediates Syncrip recognition and exosomal partitioning of miRNA targets

Exosomal miRNA transfer is a mechanism for cell–cell communication that is important in the immune response, in the functioning of the nervous system and in cancer. Syncrip/hnRNPQ is a highly conserved RNA-binding protein that mediates the exosomal partition of a set of miRNAs. Here, we report that Syncrip’s amino-terminal domain, which was previously thought to mediate protein–protein interactions, is a cryptic, conserved and sequence-specific RNA-binding domain, designated NURR (N-terminal unit for RNA recognition). The NURR domain mediates the specific recognition of a short hEXO sequence defining Syncrip exosomal miRNA targets, and is coupled by a non-canonical structural element to Syncrip’s RRM domains to achieve high-affinity miRNA binding. As a consequence, Syncrip-mediated selection of the target miRNAs implies both recognition of the hEXO sequence by the NURR domain and binding of the RRM domains 5′ to this sequence. This structural arrangement enables Syncrip-mediated selection of miRNAs with different seed sequences.
Exosomes are small, cell-secreted vesicles that carry specific repertoires of proteins and RNAs to recipient cells. This selective transfer of proteins and RNAs in the exosomal cargo represents an important means of inter-cellular communication. Exosome-mediated microRNA (miRNA) transfer is thought to be important in various processes and systems, including the immune response and neuron-glial communication. In addition, it has been implicated in a number of diseases, including cardiomyopathies, neurological diseases and cancers. Exosomal miRNA delivery in cancers mediates the communication between the tumour and stromal compartments. For example, it has been shown that the exosomal miRNAs in the brain microenvironment downregulate PTEN (phosphatase and tensin homologue) in nearby tumour cells.

The selectivity of miRNA loading encodes the inter-cellular message carried by the exosome and a key question in the field is how this selectivity is determined at the molecular level. Recent reports have shown that loading of specific miRNAs is mediated by RNA-binding proteins, four of which have been identified so far. Two of them, hnRNPA2B1 (the first such protein to be identified and a close relative of hnRNPA1), a protein known to be involved in miRNA regulation, and Syncrip, select the target miRNAs based on the presence of short G-rich RNA sequences, which are different for the two proteins. For the other two proteins, HuR, that has been linked to miRNA function before and YTBX1, no target sequences have been identified. Importantly, hnRNPA2B1, YTBX1 and Syncrip each have multiple miRNA targets. This is consistent with a model whereby a gene regulatory signal carried by the exosome can be encoded by an ensemble of miRNA molecules that are working synergistically and that are loaded by a single regulatory RNA-binding protein. However, we have no molecular information on how these RNA-binding proteins recognise miRNA targets and mediate their exosomal localisation.

Syncrip is a conserved RNA-binding protein important in neuronal and muscular development in Drosophila and mammals. Mis-regulation or dysfunction of Syncrip is associated with severe cardiomyopathies and neuro-degenerative disorders. In the fly embryo, Syncrip is important for the morphology and growth of the neuromuscular junction and regulates cytoplasmic vesicle-based messenger RNA (mRNA) transport. In mammals, Syncrip exerts control on the length and number of neurites in mouse embryonic cortical neurons as well as the growth of nascent axons, among other functions. At the molecular level, Syncrip recognises a diverse range of RNA sequences, including UACCU-containing sequences and polyA, sequences, and regulates mRNA editing, transport, translation and degradation. Importantly, we showed that Syncrip recognises an hEXO (GGCU/A) sequence in a set of miRNA targets and mediates their exosomal enrichment. However, how Syncrip recognises its diverse ensemble of mRNA and miRNA targets is not known. Syncrip contains three conserved RRM domains, which are putative RNA-binding units, flanked by a highly conserved N-terminal domain reported to mediate the interaction with Apobec protein, and a long, unstructured, less conserved C-terminus, which has been reported to mediate the interaction with synaptotagmins and a G-quartet. Considering the multiplicity of Syncrip RNA-binding domains and the diversity of its RNA targets, it seems plausible that several domains contribute to Syncrip’s miRNA and mRNA binding, as observed for other multi-domain RNA-binding proteins.

This study explains how Syncrip’s structure and mode of RNA interaction underpins its ability to recognise a set of miRNA targets with different seed sequences to be localised onto exosomes. We identify a cryptic RNA-binding unit that recognises RNA with high-sequence specificity and show that this non-canonical RNA-binding domain is responsible for hEXO recognition in Syncrip-mediated exosomal miRNA partitioning. We also show that the domain is functionally and physically coupled by a structural element to a second RNA-binding region comprising the RRM domains, and that the coordinated interaction of multiple Syncrip RNA-binding domains is the basis of efficient recognition of the full-length miRNA. We also discuss the role this binding mode may play in the interaction with the Syncrip mRNA targets.

Results

Syncrip N-terminal and RRM regions interact with RNA. Data from a number of independent studies indicate that Syncrip binds to a broad range of mRNA targets by recognition of a diverse set of sequences. As a first step to identifying the domains of Syncrip engaged in RNA binding in living cells, we used the RBDmap data set. These data report on RNA-binding protein segments making contact with poly-adenylated RNAs within native protein–RNA complexes. They are obtained by applying ultraviolet (UV)-crosslinking to living cells, oligo d(T) capture of poly-adenylated RNAs, limited proteolysis and a second round of oligo (dT)-mediated isolation. Peptides that remain crosslinked to the RNA after this process are released by trypsin treatment and analysed by quantitative mass spectrometry. By taking advantage of this unbiased methodology we aimed to identify Syncrip’s various RNA-binding domains. As expected, seven high-confidence (FDR < 0.01) RNA-bound peptides mapped to RRMs 1, 2 and 3, suggesting that the three RRM domains function as RNA-binding domains in a cellular context. However, only one high-confidence RNA-binding peptide was identified in RRM2, suggesting that this domain either binds to or crosslinks with lower efficiency to RNA than the other two RRMs. Interestingly, we also noticed the presence of three high-confidence (FDR < 0.01) and one candidate (FDR < 0.1) RNA-bound peptides in a region immediately preceding the RRM1 domain, which implies additional non-canonical contacts with the RNA. Finally, we observed that two high-confidence and five candidate RNA-bound peptides mapped to the amino (N)-terminal region of Syncrip, overlapping with the ‘acidic’ domain that has previously been described as a putative protein-interaction unit. The presence of multiple high-confidence RNA-bound peptides in this region indicates it likely plays a role in the interaction with target RNAs in the cell.

RBDmap data can also be analysed at a global level to predict the likely RNA-binding regions within a protein, such as Syncrip. This analysis employs a shrinkage discriminant analysis trained with the RNA-bound peptides and the peptides lacking RNA-binding activity reported in the RBDmap data set (unpublished). Analysis of the Syncrip sequence with this algorithm revealed high-probability RNA-binding activities not only in the RRMs, but also in the ‘acidic’ N-terminal domain. This indicates that the N-terminal ‘acidic’ domain, although specific to Syncrip protein, contains patterns of short sequences often associated with RNA-binding sites in other proteins.

Syncrip N-terminal and RRM domains are joint by an αββ motif. In order to investigate the non-canonical N-terminal RNA-binding region of Syncrip and to provide a structural framework for our studies, we set out to determine the structure of the N-terminal region of the conserved N-terminal ‘acidic’ and RRM1 domains (NeR1 construct) in Human and Drosophila Syncrip proteins. The Drosophila protein crystallised in space group P2_1 with two copies in the asymmetric unit. The 2.2 Å resolution X-ray structure (Fig. 2a)
was solved by single-wavelength anomalous diffraction (SAD) using a seleno-methionine derivatised protein. The final $R_{\text{work}}$/ $R_{\text{free}}$ are 17.4% and 20.6%, respectively, and details of the structure solution and refinement are presented in Supplementary Table 2.

The structure comprises residues G22–P243 but is missing residues 106–120, which form the linker between the N-terminal ‘acidic’ and the RRM domains and are likely disordered in the crystal. The N-terminal region is organised as a two-domain unit, with the alpha-helical N-terminal ‘acidic’ domain connected to a

**Fig. 1** Syncrip interacts with mRNA targets using multiple RNA-binding domains. **a** Schematic of the domain organisation and sequence conservation of Syncrip protein from Drosophila and human. The domains are drawn as coloured rectangles and the sequence identity between Drosophila and human individual domains is shown below each equivalent pair. **b** Workflow of the RBDmap assay. **c** Mapping of the RNA-binding sites detected in human Syncrip by RBDmap. Top: $x$-axis represents Syncrip from N- to C-terminus. $y$-axis represent the fold change between the RNA-bound (i.e., peptides crosslinked to RNA) and released (i.e., peptides released to the supernatant after protease treatment) fractions. RNA-bound peptides identified with FDR < 0.01 are depicted as red lines. Candidate RNA-bound peptides (FDR < 0.1) are depicted in salmon. Peptides released to the supernatant after proteolytic treatment are depicted in cyan. Middle: sequence propensity to bind RNA based on the superset of RNA-bound peptides of human RBPs identified by RBDmap. This prediction was performed by shrinkage discriminant analysis employing a binary classifier, which consists of the sequences of the RNA-bound peptides (positive examples) and that of the peptides lacking RNA-binding activity (negative examples). Resulting algorithm was applied to identify the regions of Syncrip with high probability to interact with RNA. Bottom: lines indicate the different domains of Syncrip, as a reference. The colour of the line(s) corresponds to the colour of the domains in panel **a**. In addition, the conserved RNA-binding sequence N-terminal to the canonical RRM1 fold domain is indicated by a yellow line. **d** Sequence alignment of the N-terminal region of Syncrip. The coloured lines below the sequences define the boundaries of the domains as reported in **a** and **c**.
classical RRM fold by an αββ structural element (Fig. 2a, b and Supplementary Fig. 1a). The conformation of the RRM, together with the orientation of the two domains and the inter-domain surface are essentially identical when comparing the two copies in the crystal asymmetric unit (Supplementary Fig. 1). However, the two copies show minor differences in the N-terminal ‘acidic’ domain, which has also higher temperature factors. Examination of individual domains reveals the N-terminal ‘acidic’ domain folds into a 5-helix bundle (Fig. 3a) with a hydrophobic core formed predominantly by leucine residues and a surface where 13 basic and 15 acidic residues create a network of interactions (Supplementary Fig. 2). This structure is consistent with that recently reported for the isolated N-terminal domain, which has also higher temperature factors. Examination of the two-domain structure also reveals that the RRM1 domain is flanked by a N-terminal αββ module (Fig. 2a, b and 3d, e) to create an extended RRM (eRRM) fold. The structure of this extended fold shows that packing between the extension and the RRM is mediated mainly by hydrophobic contacts between the eβ2 and β2 strands and between the eα1 and α1 helices with a small number of hydrogen bonds and one salt bridge also contributing (Fig. 3f, g). Within the interface, the hydrophobic side chains of the amino acids of the extension and core domain are inter-digitated and their packing buries a large (1640 Å²) solvent-accessible surface. This likely explains our observation that the RRM1 domain is not expressed in a soluble form in E. coli. Finally, inspection of a sequence alignment of Syncrip family members also reveals a large degree of sequence conservation in this region of the proteins further supporting the idea that the αββ extension is a defining feature of the Syncrip family (Fig. 3h).

The structure revealed that the interaction between the N-terminal ‘acidic’ domain and the eRRM1 is mediated largely by the last helix of the N-terminal domain (α5) making contacts with the αββ RRM-extension, and specifically with residues of the first β-strand (eβ1). Additionally, residues of the core RRM β1-β2 loop also make contact with the N-terminal ‘acidic’ domain (Fig. 4a, b). The domain–domain contacts are largely hydrophobic, but do include two hydrogen bonds (Fig. 4b). The residues involved in these interactions are conserved from Drosophila to humans (Fig. 4c) which, considering that the individual domains are stable and soluble in solution, indicates that the contacts are functionally important. However, in contrast to what was observed for the interaction between the αββ element and the core RRM1, this interface is not tightly packed and the interaction buries only 699 Å² of solvent-accessible surface.

We wondered whether, in solution, the two domains interact in the same orientation as that observed in the crystal, and whether this interaction represents a rigid and unique conformation. In order to address these points, we first used 15N-correlation nuclear magnetic resonance (NMR) spectroscopy to assess differences in the amide resonances (i.e., the chemical shift perturbation, CSP) of the two domains in isolation (N and eR1 constructs) (Table 1) and in the context of the two-domain construct. A comparison of the spectra showed that significant changes were only found in residues that are part of the interaction surface in the X-ray structure, indicating that a conformer with this surface of interaction is highly populated in solution and it is likely that an equivalent inter-domain interaction is taking place in solution and in the crystal (Fig. 4d). Next, we assessed whether the two domains are locked together in a unique orientation. First, we used 2H,15N heteronuclear NOEs to evaluate which regions of the di-domain were the most flexible. The NOE values (Fig. 4e) indicated that the two linkers joining the αββ unit to the N-terminal domain and the core RRM are undergoing significant high-frequency motions. Indeed, these linkers do not participate in the inter-domain interactions observed in the crystal structure. We then determined the rotational correlation time (τc) of each of the domains within the two-domain construct (Fig. 4f). Surprisingly, we observed a significant difference in τc (τc of the N-terminal domain is 10.0 ± 0.9 ns, τc of the extended RRM1 domain is 11.8 ± 1.0 ns) that indicates that the two domains are not tightly coupled. The dynamic nature of the relationship between the domains was confirmed using a second NMR observable. We measured the 15N amide residual dipolar couplings (RDCs) for the two-domain construct and compared the experimentally measured RDC values to the RDC values back-calculated from the crystal structure using either a single tensor for the two domains or two independent tensors, one per domain; the latter representing a molecule where the domains are not tightly coupled. The dynamic nature of the relationship between the domains was confirmed using a second NMR observable. We measured the 15N amide residual dipolar couplings (RDCs) for the two-domain construct and compared the experimentally measured RDC values to the RDC values back-calculated from the crystal structure using either a single tensor for the two domains or two independent tensors, one per domain; the latter representing a molecule where the domains are not tightly coupled. This comparison (Fig. 4g, h) shows that the RDC set calculated from a two-tensor fitting, but not the one calculated from a one-tensor fitting, correlates well with the experimentally measured set. The RDC data indicate that the structure of the individual domains is the same in solution and in the crystal, but also that the domains are not locked together in a unique orientation. To further validate that the conformation observed in the X-ray structure is compatible with the solution data we carried out a data-driven molecular docking protocol with HADDOCK31,32 employing the CSP and RDC data. The resulting models cluster in two main families (see Materials and methods), with the largest, lower energy family superimposing closely with the crystal structure (Supplementary Fig. 2), while in the second smaller family, the surface of interaction is very similar but the orientation of the two domains is 180-degree rotated. Notably, a single set of RDC data does allow for symmetric positioning of the NH vectors, which would explain the inter-domain orientation in this second

family and so it seems likely this second family is an artefact that reflects the limits of the solution data. Altogether, the HADDOCK modelling and solution data indicate that the X-ray structure represents a highly populated conformer in solution and that the interaction between the two domains is specific but dynamic with the domains spending a non-negligible part of the time detached. An important question is how the coupling we observe between the two domains is linked to protein function and target recognition.

Syncrip N-terminal domain is a conserved RNA-binding domain. The N-terminal ‘acidic’ domain of Syncrip is conserved throughout evolution (Fig. 1c), although it has no close structural homologue outside the Syncrip family. The domain has been reported to be essential for the interaction with the cytosine deaminase APOBEC133 and, also based on a predicted overall neutral. In order to obtain some initial information on the determinants of the N-terminal domain’s functional interactions, we mapped the conserved residues on the domain structure (Fig. 5a). These data revealed a large conserved surface likely to be important for the interaction with its functional partners. This surface is centred on a patch of positive and hydrophobic amino acids (Fig. 5a and Supplementary Fig. 3) and is, therefore, a good candidate to mediate the mRNA interaction identified in the mRNA capture assays. This was tested using NMR spectroscopy, initially on a construct including the N-terminal domain only (construct N). As the RNA sequence recognised by the domain was unknown, RNA binding was initially investigated by titrating short randomised oligonucleotides of increasing length (4 and 5 nucleotides that we name 4N RNA and 5N RNA) into the protein and monitoring the binding using the CSP observed in $^{15}$N-correlation fingerprint NMR experiments. Titration with the
different RNA oligos changes the position of selective amide resonances from residues in two of the five helices (Helices 3 and 5) that are part of the domain’s conserved surface (Fig. 5b). Further, this RNA-binding surface is unchanged in titration with 4N RNA and 5N RNA.

Next, we wanted to determine whether RNA recognition by the domain, which we designated NURR, is specific and whether this specificity is conserved during evolution. In order to define the sequence specificity, we performed scaffold independent analysis (SIA)34 on both Drosophila and human Syncrip. SIA examines the sequence specificity of RNA-binding domains mediating moderate affinity interactions. The method is based on the comparative analysis of the binding of a protein to quasi-degenerate sets of RNA pools using NMR spectroscopy. For each position of an RNA sequence to be examined four pools are used where a single position is occupied by either an A, U, C, or G while the other positions are occupied by a randomised mix of the four bases. NMR is used to assess the binding of the four pools to the protein in a comparative fashion and the comparative SIA assay5 reported (Fig. 5c) represent the relative preference for a base with respect to the others in a specific position. Our SIA assays delivered an unbiased report of the nucleobase preferences of the domain in human and Drosophila (Fig. 5c). These SIA data revealed that, in Drosophila, the NURR domain recognises a C in the bound sequence at position 2 with very high specificity, while the nucleotides in positions 1 and 3 are bound with lower specificity (Fig. 5c). Importantly, and in contrast to the Drosophila protein, human Syncrip recognised a G in both the first and second bound position (Fig. 5c) and discriminates against U in the third bound position, which has much lower specificity. These data suggest that the human and Drosophila proteins bind RNA with the same surface but interact with different sets of targets.

To complement this analysis, we explored RNA binding by the eRRM domain (construct eR1), where the canonical RRM $\beta$-sheet RNA-binding surface is extended by the two $\beta$-strands of the $\alpha\beta\beta$ element. This surface is highly conserved (Figs. 1d and 6a), and includes the aromatic residues in the RRM’s RNP1 and RNP2 motifs associated with canonical RNA binding. Chemical shift changes in $^{15}$N-correlation NMR spectra recorded with different RNA pools confirmed that this conserved surface mediates RNA binding (Fig. 6b), although the fast exchange regime and relatively small chemical shifts observed suggests the interaction made by the isolated eRRM1 domain is not of high affinity.

Notably, in the crystal structure the conserved RNA-binding surfaces of the RRM and NURR domain are aligned by the physical coupling between the two domains (Fig. 6c), providing a first rationale for this coupling. This creates a single di-domain surface for RNA recognition where a canonical RRM-RNA binding mode positions the RNA in a 3’ (NURR-bound) to 5’ (RRM-bound) orientation. The RRM domains of Syncrip are joined by very short linkers and, arguably, the $\alpha\beta\beta$ extension of RRM1 connects RNA binding by the NURR domain to that of the entire RRM region of the protein.

**NURR domain–hEXO RNA interaction mediates miRNA recognition.** Our recent work has shown that Syncrip recognises a GGCU/A (hEXO) sequence present in a group of miRNAs, and that this interaction directs the loading of these miRNAs into exosomes10. Indeed inserting this sequence in a non-target miRNA (mir29a-1) leads to its exosomal loading10. Our present study shows that the human NURR domain recognises, with high specificity, a GG sequence that matches the core nucleotides of the hEXO sequence (Fig. 5c), and we hypothesise that the
NURR–hEXO interaction provides a key element for Syncrip-miRNA recognition.

To test our hypothesis, we first examined the NURR–hEXO interaction in isolation using NMR and confirmed that the short hEXO RNA binds to the conserved RNA-binding surface of the domain by monitoring chemical shift changes during a titration of the protein with the RNA and mapping the perturbed resonances on the domain structure (Fig. 7a–c Supplementary.
Fig. 4). Then we performed an equivalent titration using a 4-domain hSyncrip construct containing the NURR domain plus the three RRMs (NeR1R2R3). Although the spectral quality of the larger protein is, as expected, lower, the comparison of the two titrations showed that none of the distinguishable resonances of the three RRMs changed upon RNA addition (Fig. 7a, d and Supplementary Fig. 5, see also the later comparison with the RRM resonance shifts obtained by binding a full-length miRNA). Instead, equivalent changes are observed in the amide resonances of the NURR domain upon RNA binding in isolation and within the larger protein (Fig. 7a, d and Supplementary Fig. 5). This indicates that the RNA selects specifically the NURR domain over the three RRM domains and the features of the interaction do not change in the context of the four-domain protein, confirming the importance of the specific NURR–hEXO RNA recognition (Fig. 7a, d).

In order to establish a direct link between the NURR domain and Syncrip recognition of the hEXO sequence within a full-length miRNA target we used biolayer interferometry (BLI) assays. As a model we chose miR-3470, the miRNA that (i) is most efficiently pulled down by Syncrip after crosslinking and (ii) shows the strongest change in exosomal partitioning upon silencing Syncrip. First, we compared the binding of the four-domain RNA-binding region of Syncrip (NeR1R2R3) to wild-type full-length miR-3470 and to miR-3470 with a mutated hEXO sequence, and showed that mutation of the hEXO sequence decreases the binding affinity ~6-fold (Fig. 7e). This experiment established that our in vitro assays can discriminate between cognate and non-cognate targets. Then, we showed that recognition of the hEXO sequence is dependent on the presence of the NURR domain, as the eR1R2R3 construct, that does not contain the NURR domain, can no longer discriminate between wild-type and mutated miR-3470 in a BLI titration of the RNA with the three-domain construct (Fig. 7f). It is worth mentioning that mutation of the hEXO sequence and removal of the NURR domain lead to the same decrease of affinity.

Finally, we tested whether RNA binding by the NURR domain affects the specific recognition of the RNA targets in the cellular environment. To probe this, we used both a protein construct where the NURR domain had been deleted (ΔNURR) and a variant of the domain where RNA binding has been eliminated through the introduction of two point mutations that do not change the protein structure. These structure-driven mutations changed a positively charged side chain in the RNA-binding surface to alanine (R60A) and introduced a bulky hydrophobic side-chain to disrupt protein–RNA packing (G97L) (Fig. 8a). Modelling of these changes on the protein structure indicated that the mutated side chains are unlikely to interfere with the protein fold (Fig. 8b), and we tested both the RNA-binding function and structure of the double mutant using NMR spectroscopy. For these assays, we used the two-domain construct as the G97 residue is close to the interface between the NURR and extended RMM1 domains. Superimposition of the NMR spectra of the NeR1 construct, wild-type and mutated confirmed that the double substitution does not change the structure or destabilise the protein. Titration of the mutant with the hEXO sequence confirmed that the double mutation impairs the interaction with the RNA at 50 µM concentration and 1:4 protein: RNA ratio (Fig. 8c). Then, the selective binding capacity in the cell of human WT Syncrip was compared to that of the NURR domain deletion and R60A/G97L mutants using RNA-immunoprecipitation (RIP) after UV-crosslinking, that reports directly on protein–RNA interactions. RIP analysis (as in Santangelo et al.) of miR-3470 and the negative control non-hEXO miR-92a-1-1p was performed using extracts of cells silenced for endogenous Syncrip expression after introduction of WT Syncrip, Syncrip ΔNURR or Syncrip R60A G97L by retroviral transduction. As shown in Fig. 8d, the capacity of both mutants to immuno-precipitate the hEXO-containing miR-3470 is impaired with respect to the WT full-length protein, confirming the key role of the NURR domain in the recognition of the miRNA targets.

The NURR–RRM coupling is important for RNA target selection. Our previously published cellular assays identified the hEXO sequence as the only sequence required for exosomal miRNA partitioning. However, the structural work we present here indicates that RRM and NURR binding surfaces are coupled and that this coupling is likely to play some role in the interaction. One question is whether this role is exclusively to increase the affinity of the interaction or whether binding of the RRM domains may contribute to selectivity in a non-sequence-dependent fashion, i.e., by providing some previously hidden structural restraint. To de-convolute the two possibilities we have obtained a mechanistic model for protein–RNA recognition. As first step, we assessed the contributions of the NURR and RRM domains to overall affinity. Our BLI and NMR data so far show that the NURR domain interacts with the isolated hEXO sequence with a weak-to-intermediate affinity and we wanted to test whether this applies also in the context of a longer RNA target. Using BLI, we measured a 29 µM Kd for the interaction between the NURR domain and a miR-3470-derived 14-nucleotide RNA (Fig. 9a and Supplementary Fig. 6), confirming that the domain binds to the RNA target with moderate affinity. By contrast, the four-domain NeR1R2R3 protein binds the full-length miR-3470 with very high affinity (Kd ~ 2.0 nM) (Figs. 7e and 9a). The four orders of magnitude increase in binding affinity indicates that the RRM domains are essential for a high-affinity interaction. Further, the physical coupling between the NURR and eRRM1 domains determines the direction of binding of these domains along the RNA molecule, positioning the NURR domain 3’ to the RRMs. All-together data show that the NURR and RRM domains cooperate to achieve a selective, high-affinity Syncrip-miR-3470 interaction, implying that the RRM domains must bind 5’ of the hEXO sequence, which is here
located at the 3′ end of the miRNA. We then titrated the four-domain protein with the full-length miR-3470 and monitored the binding using 15N-correlation NMR spectroscopy. The NMR spectra show that the interaction between the RRM region and the miRNA involves both RRM1, RRM2, and RRM3 (Fig. 9b, c). We discuss below how the cooperation and positioning of the NURR and RRM units on the miRNA targets is related to the selection of a set of hEXO miRNAs with different seed sequences in the cell.

Discussion

The loading of selected miRNAs into exosomes is a recently discovered mechanism for cell–cell communication that is
important to the development and function of a broad range of tissues. Selectivity in miRNA loading is mediated by RNA-binding proteins, which recognise specific sequences on the target miRNAs. Here, we have focussed on the Syncrip protein to investigate the molecular basis of the selection of its miRNA targets. Syncrip is an abundant and conserved RNA-binding protein that binds both mRNA and miRNA targets and regulates mRNA transport, editing and translation degradation, as well as miRNA partitioning in the exosomes. However, to date we do not have a quantitative and mechanistic understanding of how RNA is targeted and regulated by Syncrip. This understanding is crucial to gain insight into the mechanistic basis of Syncrip-mediated exosomal partitioning of miRNAs.

The output of our RBD analysis indicates that the three RRM domains in the central region of Syncrip cross-link to RNA in vivo. Unexpectedly, the N-terminus of Syncrip, which includes an N-terminal domain and a conserved sequence N-terminal to RRM1, also interacts with RNA. As a first step to understanding Syncrip-RNA binding at the molecular level, we determined the crystal structure of this non-canonical RNA-binding region. The structure shows that the N-terminal and RRM1 domains are brought together by an αβα structural element created by the folding of the highly conserved sequence amino-terminal to RRM1. One question is whether and how this coupling is functionally relevant. The αβα motif aligns the two highly conserved RNA-binding surfaces of RRM1 and NURR to create one continuous RNA-binding surface and to establish the direction of how the NURR and RRM(s) position on the RNA target, providing a first indication that the physical coupling between domains is likely to be important to Syncrip RNA binding.

Unexpectedly, our work shows that the N-terminal NURR domain of Syncrip is a RNA-binding domain with a highly conserved RNA-binding surface. Further, our SIA assays and titration analyses show that RNA binding by the NURR domain is sequence specific, consistent with a direct role in the selection of Syncrip target RNA recognition. Indeed the NURR domain binds to the hEXO motif (GGCU), whose recognition by Syncrip mediates exosomal partitioning. BLI data confirm that Syncrip specifically recognises the hEXO sequence within the miR-3470 target and that the removal of the NURR domain impairs this Syncrip-hEXO recognition. These assays directly relate hEXO-mediated miR-3470 recognition to the hEXO-NURR interaction, explaining the molecular basis of the reported miRNA target selectivity. This result was tested to the cellular environment with the design of the double mutant where the RNA-binding function of the protein is selectively impaired.

**Fig. 5** The N-terminal domain of Syncrip is a novel sequence-specific N-terminal unit for RNA recognition (NURR). a Residues conserved (identical) in human and Drosophila are coloured in red on the structures of human (PDB ID: 2MXT) and Drosophila Syncrip (this study) N-terminal domains. The smaller images show 180° rotations of the structures. b Chemical shift changes upon binding the randomised 4N RNA are mapped in blue on the surface of the NURR domains. The smaller images show 180° rotations of the structures. c SIA scores for the human and Drosophila NURR domain, reflecting the nucleobase preferences at the different positions of the bound sequence. In this representation, the relative height of the four columns in each position represent the relative preference of the domain for the four nucleobases
When tested using RIP assays, abolition of NURR RNA-binding function also resulted in a loss of miR-3470 pulldown confirming that RNA binding by the NURR domain is essential for target recognition in the cell. It is worth highlighting that the sixfold effect on binding affinity we observe in our in vitro two-component system translates into a loss of binding in our cellular assays. This emphasizes how relatively modest changes in the affinity for an RNA target may result in drastic changes in the protein–RNA association in the cell, where other proteins and RNAs are competing for interacting partners.

A second question important to understanding Syncrip–miRNA recognition is whether the NURR domain is a stand-alone high-affinity, high-specificity miRNA recognition element that mediates the interaction with the miRNA targets, or whether and how the RRM domains contribute to the interaction. We show that, in isolation, the NURR domain binds to the miRNA target with moderate affinity (∼29 µM $K_d$), while high-affinity binding (∼2.0 nM $K_d$) to the target miRNA requires the additional interaction of the RRM domains. That is, the NURR and RRM domains act together to achieve a specific and high-affinity interaction with the Syncrip RNA targets. Importantly, the contacts between the NURR and eRRM1 domains position the RRM domains 5′ of the NURR domain on the bound RNA sequence. This provides a previously hidden structural constraint and implies that for Syncrip to interact with a target miRNA with high-affinity and specificity the hEXO sequence cannot be positioned at the 5′ end of the miRNA. The 5′ end of a miRNA molecule is occupied by the seed sequence, which is the main determinant of target recognition in canonical miRNA–mRNA target interaction, while sequences 3′ of the seed are less functionally constrained. Arguably, this mutational freedom would facilitate establishing a regulatory sequence (the hEXO sequence) common to a set of miRNAs with different targets. Therefore, we revisit the rules of recognition previously drawn and that propose the architecture of the RNA-binding region of Syncrip underpins its ability to recognize a common sequence in miRNAs with very
**Fig. 7** The NURR domain mediates the specific recognition of miR-3470 hEXO-motif. 

a. Binding of the NURR domain to the AGGCU hEXO-motif monitored by NMR. Left: superimposition of the free (black) and RNA-bound (1:1 ratio, red) protein spectra. Right: zoom of the boxed region. Residues names are annotated. 

b. Residues whose amide resonances are affected by the binding of the hEXO RNA are mapped in blue on the surface of the NURR domain. 

c. Residues with significantly perturbed resonances upon hEXO binding are indicated with an asterisk above the sequences of the human and Drosophila proteins. 

d. Binding of the four-domain NeR1R2R3 construct to the AGGCU hEXO-motif. Left: superimposition of the free (black) and RNA-bound (1:1 ratio, orange) protein spectra. Right: zoom of the boxed region. Residues names are annotated as in b. 

e. Binding of the four-domain (NeR1R2R3) protein to wild-type miR-3470 (hEXO) and mutant miR-3470 (ΔhEXO) monitored by BLI. The hEXO and mutated sequences are highlighted in the inset in blue and red, respectively. BLI response values are plotted against the protein concentrations and normalised for better comparison. Dissociation constants are reported. 

f. Binding of the three-domain construct (eR1R2R3) lacking the NURR domain to wild-type and mutant miR-3470, as in e. In the absence of the NURR domain, the protein no longer recognises the cognate RNA.
Fig. 8 Eliminating the RNA-binding activity of the NURR domain impairs Syncrip interaction with miR-3470 in the cell. a Surface representation of human Syncrip N-terminal domain, residues affected by RNA binding are coloured blue and the two mutated residues coloured orange. b Model of Syncrip NeR1 R60A G97L mutant. The side chains of residues A60 and L97 are coloured red. The central image shows a cartoon representation of the protein, the two side panels show the side chains of residues close to the mutations in space filling representation. The model was built using SwissMode, using the structure of the Drosophila NeR1 two-domain protein as template, as the G97 residue is close to the N-eR1 interface. c The R60A G97L double mutation does not change the structure of the protein but impairs RNA binding. (Left) Superimposition of the $\delta^{15}$N-correlation spectra of the wild-type (blue) and mutant (orange) NeR1 protein, showing that only minor changes are observed upon mutation and that the structure of the protein is conserved. d The R60A G97L double mutation eliminates RNA binding by the N-terminal domain. The changes in a representative peak of the wild-type (top) and mutant (bottom) proteins upon addition of a 1:1 and 1:2 ratio of hEXO RNA targets are displayed in this spectral superimposition. Peaks in the RNA-binding surface change upon titration of the RNA into the wild-type, but not the mutant protein. e RIP assays with anti-SYNCRIP antibody and, as control, preimmune IgG, on lysates from hepatocytes knocked-down for endogenous Syncrip by short-hairpin RNA (shRNAs) approach (shSyncrip). A scrambled shRNA was used as control (shCTR) as previously reported10. The cells were transduced with either an empty vector (Vector) or vectors overexpressing human WT Syncrip (full length), human ΔNURR (dTNR) and human mutant Syncrip (R60A-G97L). miRNA 3470a (left) and miRNA 92a-1-5p (right) (hEXO miRNA and non-hEXO miRNA, respectively) levels in immune-precipitated samples were determined by RT-qPCR and reported as IP/IgG. Data are means ± SEM of three independent experiments. Statistical significance was determined by parametric paired t-test analysis (*p < 0.05).
different seed sequences and to efficiently regulate a group of miRNAs with very different target specificities.

It is worth mentioning that, in addition to recognising the hEXO sequence, the NURR domain makes contact with mRNAs in our mRNA interactome pull down experiments. Interestingly, in Drosophila the domain recognises a C with high specificity in a central position of the sequence (Fig. 5c). The different specificity observed for the human and Drosophila proteins indicates that the highly conserved N-terminal domain of Syncrip has maintained its RNA interaction surface but has dramatically changed its sequence specificity during evolution, arguably to adapt to different sets of RNA targets. An open question, also relevant to a number of other multi-domain RNA-binding proteins, is how the different classes of RNA targets have contributed to define Syncrip’s structure and sequence specificity. As a first step, when the RNA interactome of the two proteins becomes available it would be interesting to assess how differences in the RNA target sequences of the human and Drosophila Syncrip relate to changes in the specificity of the different domains of the protein, also relate these differences to structure using recent methods for unbiased structural analysis of RNA-binding proteins.

This work examines the molecular basis of target selection in Syncrip-mediated exosomal miRNA loading and finds that
recognition of the miRNA targets is, unexpectedly, mediated by the cooperation between a NURR RNA-binding domain and three RRM domains. In the case of hnRNP2B1, the first protein to be reported to mediate exosomal partitioning of selected miRNAs target selection depends on the recognition of a short sequence found mainly in the 3′ end of the miRNA, and the protein contains two RNA-binding RRM domains. We future work will explore whether the Syncrip and hnRNP2B1 proteins adopt a similar strategy of miRNA recognition, and future work will investigate how the high-affinity interaction between Syncrip and the target RNA is regulated.

Methods

**Plasmids for protein production.** The genes encoding D. melanogaster Syncrip isoform F (UniProt AAV364) and human N-terminal H. sapiens Syncrip/hnRNPA12 (UniProt O60506, DNA purchased from GenScript) (Supplementary Table 3) were inserted into pET-52 SUMO or pET-5274 using Ligation Independent Cloning (LIC) to produce an HRV 3C cleavable amino-terminal HisSUMO and Hisfusin as described previously in ref. **8**. For in vitro studies, the hSyncrip NeR1 R60A G97L double mutant protein was produced using the Quikchange Site Directed Mutagenesis Kit (Agilent) and the wild-type protein expression vector as template. Mutants of the full-length hSyncrip for eukaryotic expression were prepared using the Quickchange protocol (primers sequences in Supplementary Table 4) employing the retroviral pCLX plasmid (as described in Santangelo et al. **10**) expressing the wild-type gene as template. The sequences of all constructs were confirmed by DNA sequencing prior to expression.

**Protein expression and purification.** The human and Drosophila Syncrip proteins were expressed in the E. coli strain BL21 (DE3) Gold (Agilent) and purified using the same protocol. Bacterial cultures were grown at 37 °C to a density of 0.5 of carbon and nitrogen.

**Protein backbone assignment experiments.** Backbone resonances assignments for **H**, **13**N, **13**Ca and **13**Cb, and **15**C chemical shifts of the dSyncrip N and NeR1 constructs were obtained from standard HNCA, CBCA(CO)NH, HNCO, HNCA and HN(CA)CO experiments recorded on a 0.6 mM protein sample in 5 mM Tris-HCl, 50 mM NaCl, 1 mM TCEP-HCl, 0.04% NaN3 at pH 7.4. For hSyncrip NeR1 and eR1 the backbone assignments for **H**, **13**N, **13**Ca and **13**Cb chemical shifts were obtained from HNCA and CBCA(CO)NH experiments recorded on 0.6 mM protein samples in the buffer and conditions above. The **1H** and **15**N amide resonances of hSyncrip N-terminal domain and of the dSyncrip eR1 were assigned based on the superimposition of the spectra of the individual domains and the di-domains.

**NMR relaxation experiments and RDC measurements.** **15**T1 and T2 values and **15**N heteronuclear NOE values were obtained from standard experiments **22** recorded at 600 MHz **1H** frequency on 0.3 mM samples of dSyncrip NeR1 and eR1 proteins, respectively to 10, 100, 200, 400, 500, 750, 1000, 1250, 1500 ms delays and 9, 18, 27, 36, 45, 63, 81, 100 ms delays were used, respectively, for **T1** and **T2** experiments recorded on dSyncrip NeR1. 10, 100, 200, 400, 700, 800, 1000, 1500 ms delays and 8, 16, 24, 32, 40, 48, 72, 80, 96, 120, 144 ms delays were used, respectively, for **T1** and **T2** experiment recorded on dSyncrip eR1. Heteronuclear NOE values were obtained from standard experiments **43**.

RDGs were obtained for the dSyncrip NeR1 construct. In-Phase and Anti-Phase (IPAP) experiments were recorded on a 0.3 mM sample of **15**N-labelled NeR1 in NMR buffer and filamentous phage P1 (from ASLA Biotech Ltd, Latvia). The RDC values were obtained by subtracting the reference value in isotropic solution. All data were processed with NMRSpipe and the spectra were analysed in CCPNMR analysis. Fitting of the measured RDGs to those calculated from the crystal structure was performed using the program MDMod **45**, using either one or two tensors corresponding to the two domains.

**NMR titration experiments.** NMR titrations were performed in 5 mM Tris-HCl, 50 mM NaCl, 0.5 mM TCEP-HCl, at pH 7.4. buffer recording **15**N SOFAST NMR spectra of protein–RNA complexes at the concentrations and ratios below. A 50 µM sample of dSyncrip N-terminal domain was titrated with four and five nucleotide fully randomised oligonucleotide pool (4N and 5N RNAs) at 1:4 protein:RNA ratio. A 50 µM sample of hSyncrip N-terminal domain was titrated with 4 RNA pool up to a 1:4 protein:RNA ratios. A 50 µM sample of hSyncrp N-terminal domain was also titrated with hEXO RNA at 0.5, 0.1, 1, 1.5, 2, 3, 4 and 6 protein:RNA ratios. Fifty micromolar samples of hSyncrip RRM1 and R60A G97L mutant were titrated with NNNANN, NNNCNN, NNNGNN and NNNUNN RNA (for availability we used an oligo series) at 1:4 and 1:16 protein:RNA ratios. One-hundred and twenty micromolar samples of hSynR1R2R3 were titrated with either hEXO at 0, 0.5, 1, 1 protein:RNA ratios) or full-length miR-3470 (at 0 and 1 protein:RNA ratios). Fifty micromolar samples of hSyncrip NeR1 wild-type and R60A G97L mutant were titrated with hEXO RNA at 0, 1 and 2 protein:RNA ratios.

**SiA experiments** **24** were performed on 25 µM samples of human and Drosophila N-terminal proteins. Protein–RNA ratios employed were 1:4 and 1:8, with 1:8 ratios to better match observed changes. The experiments were performed as described **44**. Briefly, NMR data were acquired using a Bruker Avance III NMR spectrometer operating at 700 MHz and equipped with a 5 mm TCI cryoprobe. Samples were stored in 3 mm NMR tubes at 4 °C within a Bruker SampleJet auto- sampler and loaded automatically after a short pre-heating 25 °C step. Locking, tuning, matching and shimming were performed automatically.

**X-ray crystallography.** Drosophila Syncrip NeR1 was crystallised by sitting drop vapour diffusion. Typically, a 3 µg mL **−1** solution of NeR1 in either gel filtration buffer or NMR sample buffer was mixed in a 1:1 ratio with mother liquor. Initial conditions were optimised and drops were seeded to produce fewer, larger crystals. The best NeR1 crystals formed in 2.2 M ammonium sulphate, 0.1 M sodium citrate pH 6 with seeding and incubation at 18 °C for 5–7 days. Crystals were protected with 20% (v/v) glycerol and frozen by direct immersion in liquid nitrogen. The crystals belong to the space group P21, with two copies of NeR1 present in the asymmetric unit (ASU). Seleno-methionine (SeMet) derived protein protocol provided by the company. Ribo-oligonucleotides were: hEXO-motif: AGCCGU, full-length miR-3470: UCAUUUUGUAGACCAUGGUCCG, 14mer miR-3470: GUAGACCAUGGUCCG and chimera miR-3470: UCAUUUGUAGACCAUGGUCCG.
was crystallised under the same conditions. The diffraction quality of the tested crystals was highly variable, often being highly anisotropic in one direction. Diffraction data sets were collected at 100 K at the I03 beamline at Diamond Light Source (Didcot, UK). The structure of NeR1 was solved by SAD using a fine-sliced data set (0.15°) of Se-Met derived protein recorded at 0.979 Å. X-ray Detector Software (XDS) was used to process the data which extended to 3.1 Å.

Detector Software (XDS) was used to process the data which extended to 3.1 Å sliced data set (0.15°) of Se-Met derived protein recorded at 0.979 Å. X-ray Light Source (Didcot, UK). The structure of NeR1 was solved by SAD using a was crystallised under the same conditions. The diffraction quality of the tested for the model was refined at a final Rwork/Rfree of 0.174/0.206 and has good geometry as determined by PROCHECK. Details of the crystal parameters and refinement statistics are presented in Supplementary Table 2, and the coordinates and structure factors have been deposited in the protein data bank (accession code: 6ES4). All structural images were generated using PyMol (The PyMOL Molecular Graphics System, Version 1.8 Schrödinger, LLC).

HADDOCK. The HADDOCK runs were performed using the GURU interface of the WeNMR/West-Life GRID-enabled web portal for HADDOCK 2.2 and standard parameters with the exception that only 5% of the input data were discarded. As experimental input parameters, all residues showing CSPs > 0.02 ppm were marked as active with HADDOCK determining the passive residues automatically. The RDC data were input with different tensor values for the NURR-domain (D = 17.7 and R 0.22) and the extrRMI1 domain (D = 18.0 and R 0.31) as obtained from the best fit of the RDC data to the crystal structure with the program PALES. Two-hundred structures were calculated that grouped into three clusters (Clusters 1,2,3 having 106,68,21 structures respectively) representing 97.5% of the structures. Cluster 1 is by far the largest and also has the overall best Haddock score (−71.4 ± 3.2), with cluster 2 having a less favourable Haddock score (−68.8 ± 1.0) and cluster 3 considerably lower score (−59.9 ± 2.5). The results compare well with the tutorial example given in ref. 53.

Bio-layer interferometry measurements. BLI experiments were performed in 5 mM Tris- HCl, 50 mM NaCl, 1 mM TCEP, 0.5 mM EGTA, 25 mM borate solution (pH 7.4) on an Octet Red 86 instrument (ForteBio, Inc. Menlo Park, CA) at a temperature of 30 °C. Biotinylated miR-3470 RNA variants (14mer, full-length and chimera) (1 ng/μl) solutions were immobilised on streptavidin-coated biosensors and incubated with varying concentrations of hNRN-P K2 (2 x dilution series, 400–6.25 μM) and Syncrip NeR2R3 (2 x dilution series, 50–0.78 nM).
