ABSTRACT

Background: Swelling and discomfort in acute knee injuries make knee clinical tests challenging and ineffective. Magnetic Resonance Imaging (MRI) could also be used to diagnose intra-articular and extra-articular traumatic lesions in the knee while Arthroscopy was the traditional gold diagnostic method for evaluating intra-articular knee injury. We proposed the study to evaluate the effectiveness of MRI in assessing the Anterior Cruciate Ligament injury in comparison to arthroscopy of the knee.

Method: Study was undertaken in the Department of Orthopaedics, Datta Meghe Hospital, Nagpur in collaboration with Datta Meghe Hospital, Sawangi, India from August 2019 to March 2020 to ascertain the need for routine MRI of the knee for assessment of an injury of the anterior cruciate ligament in sudden traumatic haemarthrosis. 16 yrs to 60 yrs age were included and intra-articular fractures, patellar dislocations, extraarticular ligamentous lesion, previous injury to the same joint, non-haemorrhagic, and haemophilias were excluded.

Results: 32 cases of acute traumatic haemarthrosis of the knee during the period from August 2019 to March 2020 were subjected to MRI examination and arthroscopic examination and findings noted on the scoring system based on The International Knee Documentation Committee (IKDC) 2000 scoring system. Total MRI positive ACL deficient patients were 18 out of 32 and total Arthroscopically positive ACL deficient patients were 13. 10 patients were ACL deficient both in MRI and Arthroscopically and 11 were having normal ACL both in MRI and Arthroscopic evaluation. Fisher exact test p= 0.0751 and Chi-square with Yates correction p= 0.1125. The sensitivity of MRI in detecting ACL injury is 76.92 in comparison to arthroscopy. In spite of the high sensitivity, the specificity of 57.89 shows there is a decreased probability of detecting true negatives. The positive predictive value is 55.55 and the negative predictive value is 78.51 with an accuracy of 65.82.

Conclusion: The cost of MRI although reduced is significant in comparison to arthroscopy. MRI with a sensitivity of 76.92 has a high index of detecting true positives. The probability of detecting true negatives is low with high false negatives. Arthroscopy examination is superior to MRI in detecting ACL injuries from the comparison with significant P-value.

Key Words: Haemarthrosis, MRI, Arthroscopy, ACL

INTRODUCTION

Swelling and pain in acute knee trauma render knee clinical examination tricky and unreliable¹. MRI is a non-invasive tool for analyzing structures of the osseous and soft tissue without using ionizing radiation. The utility of magnetic resonance imaging in evaluating knee injuries has been documented by several authors (Dandy 1997 & Boeree et al. 1991). MRI can be used in the treatment of intra-articular and extra-articular traumatic lesions in the knee while Arthroscopy was the traditional gold diagnostic method for the assessment of intra-articular knee damage²,³,⁴. The use of MRI for diagnosing intraarticular ligaments injuries is increasing due to increased demand for the same by the patients. Most surgeons tend to assume that MRI is an accurate, non-invasive type of knee injury diagnostic tool, adequate to lead to prudent medical decisions and to avoid unnecessary arthroscopic surgery⁵,⁶,⁷. MRI shows a decrease in its sensitivity in detecting ACL injury when
there are concomitant lesions in other internal structures in
the knee [Rubin et al.; 1998] and there is an increase in sen-
sitivity when interpreted by a musculoskeletal radiologist1.

MRI is being demanded by patients in our institute being
part of industrial setup and as well as it is made available at
a considerably less cost due to competitive pricing among
service providers and lastly the procedure being non-inva-
sive. Even with the competitive pricing, the amount spent on
MRI is considerable. We proposed the study to evaluate the
effectiveness of the MRI in assessing the Anterior Cruciate
Ligament injury in comparison to arthroscopy of the knee.

MATERIAL AND METHODS

The present study was conducted in the Dept. of Orthopedics
and Dept. of Radiology at Datta Meghe Medical College,
Shalinitai Meghe Hospital and Research Centre, Nagpur in
collaboration with Jawaharlal Nehru Medical College, Datta
Meghe Institute of Medical Sciences, Sawangi, (Meghe),
Waydha, Maharashtra.

Patients who had clinical testing, MRI, and arthroscopy se-
quently for suspected meniscal and ligament injuries were
considered for the present analysis, and the results were re-
viewed. Clinical data reported and analyzed include patient
demographics, waiting time between MRI and arthroscopy,
suggestive symptoms including effusion, the emergence of a
“pop,” locking, cause of injury, clinical diagnosis and surgi-
cal information. The investigator and professional orthope-
dic experts have looked at all cases. Clinical testing included
Mc Murrays’s for meniscal injury, Lachman, cruciate injury
drawer tests, and valgus and varus stress tests for the integ-
rity of collateral ligaments. A clinical diagnosis was made,
and all patients were requested for an MRI of the affected
knee. MRI has been requested for confirmation of the clini-
cal diagnosis and for further detail.

MRI tests were conducted in three different research cen-
ters with randomized patient selection. Weighted images T1
and T2 were collected in coronal, axial, and sagittal planes.
The thickness of the cuts ranged from 3 to 5 mm. The films
were viewed by qualified radiologists who were aware of the
results of the clinical evaluation as stated in the initial let-
er of reference. In a standard type, any abnormalities of the
cruciate ligaments, menisci, or hyaline cartilage were iden-
tified. The surgeon performing the arthroscopy also eval-
uated each MRI preoperatively. All arthroscopic findings
were considered accurate, and served as a reference point for
further study. To determine the reliability of the clinical and
MRI tests, statistical analysis was used to measure sensitiv-
ity, accuracy, positive predictive value (PPV), and negative
predictive value (NPV). True positives and True negatives
have been calculated on the basis of clinical conditions and
arthroscopic correlations for meniscal and anterior cruciate
ligaments (ACL), and MRI and arthroscopic correlations.
An irregular finding (meniscus, ACL) identified by MRI
and confirmed during arthroscopy surgery had a true- posi-
tive result. There were no recorded abnormalities in a true
negative test either clinically or by MRI or Arthroscopy. A
false positive was considered when a clinical examination
or MRI detected an abnormality but was not confirmed dur-
ing arthroscopic surgery. A false-negative result has both a
negative MRI clinical examination or analysis and a positive
operating outcome.

The association of clinical exam and MRI with Arthroscopy
was expressed as a percentage from the combined data of all
patients. The study confines to the ethics and was done
with the consent and full cooperation of the patients.

RESULTS

The ability of MRI and Clinical examination to diagnose in-
traarticular knee injury was compared with arthroscopy and
the results were analyzed using various statistical tests. The
final arthoscopic findings after evaluation with MRI were
accepted as the reference standard against which the MRI
and Clinical findings were compared.

The sensitivity, specificity, positive predictive value, nega-
tive predictive value, and accuracy were calculated for
Clinical and MR imaging in diagnosing the intraarticular
knee injuries in correlation with arthroscopy. The sensitiv-
ity, specificity, positive predictive value, negative predictive
value, and accuracy were calculated using Statistical Pack-
age for the Social Sciences (SSPS 25) software.

Table 1: Gender distribution of knee haemarthrosis

| Sex    | Frequency | Percent |
|--------|-----------|---------|
| Male   | 29        | 90.6    |
| Female | 3         | 9.4     |
| Total  | 32        | 100.0   |

In this study, total 32 patients were selected randomly, out of
which 29 were males.

Table 2: Side affiliation of knee haemarthrosis

| Side | Frequency | Percent |
|------|-----------|---------|
| Left | 10        | 31.3    |
| Right| 22        | 68.8    |
| Total| 32        | 100.0   |

10 patients had left knee affection while remaining 22 had
right knee affection
Mohabey et al.: A study on correlation of magnetic resonance imaging and arthroscopy in evaluation of anterior cruciate ligament injury...

Table 3: Mechanism of trauma for knee injury

| Mode of injury       | Frequency | Percent |
|----------------------|-----------|---------|
| Slip and fall        | 17        | 53.1    |
| Road Traffic Accident| 9         | 28.1    |
| Sports               | 6         | 18.8    |
| Total                | 32        | 100.0   |

Most common mechanism of injury was slip and fall followed by road traffic accident and sport activities.

Table 4a: Findings of study MRI ACL Vs Arthroscopic ACL

| Test                      | ACL  |
|---------------------------|------|
| Accuracy                  | 65.62|
| Positive predictive value | 55.55|
| Negative predictive value | 78.51|
| Sensitivity               | 76.92|
| Specificity               | 57.89|

Table 4b: True Positive, Negative and False Positive, Negative of Arthroscopic ACL

| Arthroscopic ACL | Total |
|------------------|-------|
| Positive         | 10    |
| Negative         | 8     |
| Total            | 18    |
| MRI ACL Positive | 3     |
| Negative         | 11    |
| Total            | 14    |

Table 4c: True Positive, Negative and False Positive, Negative of MRI positive ACL

| Test | True positive | True negative | False positive | False negative |
|------|---------------|---------------|----------------|----------------|
| ACL MRI finding | 10 | 11 | 8 | 3 |

Total MRI positive ACL deficient patients were 13. 10 patients were ACL deficient both in MRI & Arthroscopically and 11 were having normal ACL both in MRI and Arthroscopic evaluation. Fisher exact test p = 0.0751 and Chi-square with Yates correction p = 0.1125. The sensitivity of MRI in detecting ACL injury is 76.92 in comparison to arthroscopy. In spite of the high sensitivity, the specificity of 57.89 shows there is a decreased probability of detecting true negatives. The positive predictive value is 55.55 and the negative predictive value is 78.51 with an accuracy of 65.62.

**DISCUSSION**

Different studies have highlighted the significance of proper diagnosis in patients with knee haemarthrosis (Noyes, Paulos et al., 1980; Mariani, Puddu and Ferretti 1981). These have shown that misdiagnosed and chronic knee injuries result poorly, and Smillie (1978) has stated that: “there are few worse errors than to enclose a recently injured knee in a plaster cast without a diagnosis”.

Clinical tests used to diagnose meniscal and cruciate ligament damage have shortcomings, and accurate signs may not be reliably obtained, particularly in a crowded orthopedic clinic, and painful in an immediate or subacute presentation. Although difficult to quantify, an accurate clinical diagnosis requires practice. Magnetic resonance imaging (MRI) has completely changed the diagnosis and management of intraarticular anatomy and ligament injuries. While non-invasive and highly responsive diagnostic tools, MRI often detects early and subtle changes in soft tissue. The highly sensitive and reliable arthroscopy technique is both diagnostic and therapeutic however it is invasive.

Considering that health economics plays a significant role in patient care, many questions arise as to when and how frequently an MRI will be required after clinical testing has confirmed the diagnosis of meniscal tear or cruciate ligament rupture. Rose et al. reported that clinical evaluation in the diagnosis of meniscal tears and ACL ruptures is as successful as MRI, so they concluded that MRI is not required in patients with the clinical possibility of the meniscus and cruciate ligament tears due to its high cost. Boden et al., who concluded that if clinical examination sets out the diagnosis of meniscus injury, MRI would not influence treatment decisions.

Ruwwe et al. found that preoperative MRI in 50 percent of patients can avoid needless arthroscopy, so it is of great benefit and should be done prior to surgery. Boeree et al. suggest that clinical assessment in the treatment of medial meniscus, lateral meniscus, and ACL tear is of limited importance with a sensitivity of 67%, 48%, and 55%, respectively.
Mohabey et al. noticed that selective MRI over clinical analysis does not have an enhanced diagnostic benefit. Brooks et al. measured the agreement between pre-operative clinical / arthroscopic and MRI / arthroscopic results in a prospective sample (79% vs. 77% agreement, respectively) and concluded that MRI did not decrease the number of adverse arthroscopic procedures.

MRI is also useful for the treatment of meniscal and ligament cruciate injuries. Yet its value is still unclear in countable percentage records with incorrect outcomes and chondral defects. Arthroscopy at present remains the authoritative diagnostic gold standard.

BN Lakhar, KV Rajagopal and P. Rai et al. studied 173 patients of which 78 showed ACL tears. They reported 98.7% sensitivity, 98.9% specificity, 98.1% positive predictive value, and 98.8% negative predictive value for MRI in evaluation of ACL tear as compared with arthroscopy. Nevertheless, when other major ligament injuries are present in the knee, responsiveness is considerably diminished (Rubin et al., 1998).

Recent findings have indicated that arthroscopy can be supported by objective clinical evaluation done by a qualified doctor with positive signs alone. A normal MRI won’t be enough evidence to refuse an arthroscopy specifically in people with arthritic knees. The use of MRI as an alternative tool for clinical decision-taking should be extremely individualized. Furthermore, there is no evidence that the number of negative arthroscopies can be decreased by an MRI scan.

Boden et al. demonstrated that bypassing MRI and moving straight to arthroscopy based on their mathematical model would be cost-effective. He showed that care includes arthroscopy for up to 78 percent of the knees tested. Kocabey et al. claimed that clinical analysis in the hands of the professional orthopedic surgeon is as effective as MRI, and that MRI should be reserved for more complex and ambiguous situations.

**CONCLUSION**

MRI with a sensitivity of 76.92 has a high index of detecting true positives. The probability of detecting true negatives is low with high false negatives. MRI is not superior to Arthroscopy examination in detecting ACL injuries from the comparison with insignificant P-value. The cost of MRI although reduced is significant in comparison to arthroscopy.
