Abstract

Several preclinical studies suggested a potential benefit from combined treatment with inhibitors of epidermal growth factor receptor (EGFR) and angiogenesis, both effective in patients with advanced non-small-cell lung cancer (NSCLC). In pretreated patients with advanced EGFR wild type NSCLC, bevacizumab plus erlotinib improved progression-free survival as second-line therapy in the BeTa study and as maintenance therapy in the ATLAS trial, although the benefit was modest and did not translate into an advantage in overall survival. Disappointing results were reported with oral VEGF inhibitors plus erlotinib in pretreated patients with EGFR wild type NSCLC. On the contrary, erlotinib plus bevacizumab or ramucirumab showed a clinically relevant improvement of progression-free survival in naïve patients with EGFR mutations, leading to the approval of these two regimens as first-line treatment of NSCLC patients with EGFR mutant tumors. Several clinical studies are evaluating the feasibility and activity of osimertinib plus bevacizumab or ramucirumab. However, limits that could affect its use in clinical practice are the need of an intravenous infusion for angiogenesis inhibitors, the increased incidence of treatment associated adverse events, the exclusion of patients with tumors located in central position or at risk of hemorrhage. The identification of predictive biomarkers is an important goal of research to optimize the combined use of these agents.
Keywords
Lung cancer, angiogenesis, tyrosine kinase inhibitor, erlotinib, bevacizumab

Introduction
Angiogenesis is a crucial process for the development of almost all tumors, including non-small-cell lung cancer (NSCLC). The acquisition of the ability to induce the formation of blood vessels, also known as the angiogenic switch, is important to ensure tumor growth. In this respect, the vascular endothelial growth factor (VEGF) family plays an important role in this process. VEGF family consists of five members/ligands (VEGF-A, VEGF-B, VEGF-C, VEGF-D, and placental growth factor) and three receptors. VEGF-A (VEGF) is the most important factor involved in angiogenesis [1-3]. The three VEGF receptors include Flt-1 (VEGFR-1), KDR (VEGFR-2), and Flt-4 (VEGFR-3), with intrinsic tyrosine kinase activity induced by ligand binding and receptor dimerization [4]. In tumors, the deregulation of VEGF signaling results in blood vessel creation with anarchic organization, promotion of tumor growth and tumor cells metastasis.

Three angiogenesis inhibitors are approved in NSCLC: bevacizumab, ramucirumab and nintedanib. Bevacizumab is a monoclonal antibody that targets VEGF. It has been approved in combination with platinum-based chemotherapy for untreated patients with unresectable, locally advanced, recurrent or metastatic non-squamous NSCLC, according to the results of two randomized phase III studies: ECOG 4599 and AVAiL [5-6]. These trials included patients with non-squamous histology and without major hemorrhage risk factors. Ramucirumab is a human monoclonal immunoglobuline G1 antibody targeting VEGFR-2 and interfering with activity of different VEGF isoforms, including VEGF-A. Ramucirumab is indicated in combination with docetaxel in metastatic NSCLC with disease progression on or after platinum-based chemotherapy. Patients with EGFR or anaplastic lymphoma kinase (ALK) alterations should have disease progression on FDA-approved therapy for these targets prior to receiving ramucirumab [7]. Nintedanib is an oral triple angiokinase inhibitor targeting the angiogenic pathways mediated by VEGFR1-3, fibroblast growth factor receptors (FGFR) 1-3, and platelet-derived growth factor receptors (PDGFR): nintedanib plus docetaxel have been approved for patients with locally advanced/metastatic NSCLC of adenocarcinoma tumor histology after first-line therapy [8].

Figure 1. Synergistic effects with dual blockade of angiogenesis and EGFR. bFGF: beta fibroblast growth factor
The epidermal growth factor receptor HER-1/EGFR besides being mutated may be overexpressed in several tumors, including NSCLC. EGFR overexpression results in activation of tyrosine kinase activity, triggering intracellular pathways resulting in apoptosis blocking, cancer-cell proliferation, invasion, metastasis and neovascularization [9]. Different EGFR tyrosine kinase inhibitors (TKIs) can be used in advanced NSCLC: gefitinib, erlotinib, afatinib, dacomitinib, and osimertinib are indicated for patients with EGFR activating mutations, while erlotinib has been approved also for patients with EGFR wild type (WT) tumors pretreated with first- or second-line therapy [10-13].

VEGF and EGFR share common downstream signaling pathways and preclinical data showed that EGFR stimulation could increase VEGF expression, providing a potential hypothesis that a dual blockade of these molecular targets may have synergistic effects (Figure 1) [14-16].

This review focuses on the dual inhibition of angiogenesis and EGFR in NSCLC, discussing the results of clinical studies and the most important issues that may limit this combination in the clinical practice.

**Angiogenesis plus EGFR inhibitors in “EGFR wild type” patients**

**Bevacizumab plus erlotinib**

A number of studies have evaluated bevacizumab plus erlotinib in advanced NSCLC patients with EGFR wild type tumors (Table 1). The first clinical studies with erlotinib plus bevacizumab were conducted by Herbst et al. [17-18], in cisplatin-refractory NSCLC. A phase I/II study evaluated the dose limiting toxicity (DLT) and activity of bevacizumab plus erlotinib in 40 patients with non-squamous NSCLC, in progression after a platinum first-line treatment, regardless of EGFR status [17]. No DLTs were reported: the recommended treatment was bevacizumab 15 mg/kg every three weeks as intravenous infusion and erlotinib 150 mg/day orally. The most frequent adverse events (AEs) were rash (85% of patients), diarrhea (65%) and infection (29%). Overall, 20% of patients had a partial response (PR), while 65% had stable disease. Notably, only nine patients had enough material to proceed for an EGFR mutational analysis and in two cases a mutation was found. Thereafter, in a randomized phase II study [18], 120 patients with non-squamous NSCLC in progression after a platinum treatment were treated with bevacizumab plus erlotinib, or bevacizumab plus docetaxel/pemetrexed or chemotherapy alone. Bevacizumab plus erlotinib was better tolerated than bevacizumab plus chemotherapy: serious AEs were reported in 55%, 41% and 33% of patients in chemotherapy, bevacizumab-chemotherapy and bevacizumab-erlotinib arm, respectively. Fatigue, nausea and vomiting were commonly reported in all 3 arms. Median progression-free survival (PFS) was 4.8, 4.4 and 3 months for bevacizumab plus chemotherapy, bevacizumab plus erlotinib and chemotherapy alone, respectively. Median overall survival (OS) was 12.6, 13.7 and 8.6 months for the bevacizumab plus chemotherapy, bevacizumab plus erlotinib and chemotherapy alone arm, respectively. The risk of progression or death was 0.66 [95% confidence interval (CI): 0.38-1.16] and 0.72 (95% CI: 0.42-1.23) for patients treated with bevacizumab plus chemotherapy or bevacizumab plus erlotinib against chemotherapy alone arm, respectively. No clinically meaningful differences were found between bevacizumab-chemotherapy and bevacizumab-erlotinib arms. Interestingly, one complete response was observed in a patient with an activating EGFR mutation treated with bevacizumab-erlotinib. These promising results prompted a randomized, double-blind, phase III clinical study (BeTa Trial) to compare bevacizumab plus erlotinib with erlotinib in 636 patients with advanced NSCLC in progression after a first-line treatment [19]. Unfortunately, the addition of bevacizumab to erlotinib did not improve the OS that was 9.3 months for bevacizumab-erlotinib versus 9.2 months for erlotinib group, respectively (P = 0.7583). Furthermore, grade 5 AEs were 6% in the bevacizumab group, including two arterial thromboembolic events, and 4% in the erlotinib group. In 30 patients with EGFR-mutant tumors, the hazard ratio (HR) for OS was lower in the bevacizumab than in the control group (HR 0.44, 95% CI: 0.11-1.67). A phase III trial compared second-line erlotinib plus bevacizumab and panitumumab versus erlotinib in 297 metastatic EGFR unselected NSCLC Chinese patients, pretreated with platinum-based chemotherapy [20]. The trial demonstrated an improvement in median PFS (4.6 versus 1.9 months, in experimental and erlotinib arm, respectively, P = 0.003) and in median OS (10.4 versus 8.9 months, in experimental and erlotinib arm, respectively, P = 0.031). However, severe diarrhea and rash were more common in the experimental than in the...
control arm (24% and 26% versus 8.5% and 8.5%, respectively). The safety and activity of bevacizumab plus erlotinib in pretreated non-squamous NSCLC patients with asymptomatic untreated brain metastases were evaluated in a phase II study (BRAIN trial) [21]. However, only 24 patients were enrolled and results may have only an exploratory value: response rate (RR) was 12.5%, 6-month PFS rate 57.2% and median OS 12 months. AEs were similar to those reported with previous trials of bevacizumab; one patient had grade 1 intracranial hemorrhage. Finally, the ATLAS trial was a randomized phase III study that evaluated the efficacy of erlotinib plus bevacizumab versus bevacizumab plus placebo as maintenance therapy in 745 patients with metastatic non-squamous NSCLC, without progression after four cycles of first-line chemotherapy plus bevacizumab [22]. The bevacizumab-erlotinib combination improved median PFS (4.8 versus 3.7 months, HR 0.71, 95% CI: 0.58-0.86), but not OS (14.4 in bevacizumab-erlotinib versus 13.3 months in the bevacizumab arm, respectively, HR 0.92, 95% CI: 0.7-1.21). Moreover, adverse events, severe AEs (mainly rash and diarrhea), and AEs leading to erlotinib/placebo discontinuation were observed more frequently with bevacizumab-erlotinib combination. On this basis, due to the modest benefit in PFS, the lack of benefit in OS and the worst toxicity profile, erlotinib plus bevacizumab didn’t become a new standard of care as second-line or maintenance therapy.

*Docetaxel or erlotinib; n.r: not reached

Several studies have also been conducted with bevacizumab plus erlotinib as first-line therapy in advanced NSCLC patients unselected for EGFR status. A phase II trial in 47 patients naive for any treatment met the primary...
end-point that was the non-progression-rate (NPR) at 6 weeks, with a 75% NPR at 6 weeks [23]. However, OS was disappointing (6.9 months) and some patients experienced serious AEs, including a kidney thrombosis, a sigmoid colon perforation and thromboembolic events. The SAKK 19/05 trial evaluated the activity and feasibility of bevacizumab plus erlotinib followed at disease progression by platinum-based chemotherapy in 101 metastatic non-squamous NSCLC patients [24]. This trial did not meet the primary end-point, with a disease stabilization rate at twelve weeks of 54.5% (lower than expected). Moreover, only 63% of patients proceeded to second-line chemotherapy. A disease stabilization rate of 83.3% was observed in EGFR mutated patients (13.8% of cases). The most common AEs with the combination treatment were acne, fatigue and diarrhea. The TASK trial compared erlotinib plus bevacizumab versus chemotherapy plus bevacizumab in naïve patients with metastatic non-squamous NSCLC, unselected for EGFR [25]. At an interim analysis, PFS was significantly worse with bevacizumab plus erlotinib compared with bevacizumab plus chemotherapy arm (median PFS 18.4 versus 25 weeks, respectively; HR 2.05, 95% CI: 1.11-3.77). Moreover, only 63% of patients proceeded to second-line chemotherapy. A disease stabilization rate of 83.3% was observed in EGFR mutated patients (13.8% of cases). The most common AEs with the combination treatment were acne, fatigue and diarrhea.

Oral VEGF inhibitors and erlotinib

Erlotinib has been combined with oral VEGF inhibitors, including sorafenib and sunitinib in NSCLC patients (Table 2). Sorafenib is a small molecule targeting VEGFR-2 and VEGFR-3, rapidly accelerated fibrosarcoma (Raf), rearranged during transfection (RET), tyrosine-protein kinase Kit, FMS-like tyrosine kinase 3 (FLT-3), and PDGFR-β, with limited anti-tumor activity in NSCLC when used as a single-agent [27-28]. A phase II study compared erlotinib plus sorafenib versus erlotinib plus placebo in 168 pretreated NSCLC patients [29]. In both treatment arms the majority of patients had a non-squamous histology, was female, and already received bevacizumab in a prior line. An EGFR and Kirsten rat sarcoma (KRAS) mutation test was done in 65% of the patients and most of them were WT. The primary endpoints [overall response rate (ORR) and PFS] were similar in the two groups. Sixty-seven patients with EGFR wild-type tumors had a median PFS of 3.38 versus 1.77 months (\( P = 0.018 \)) and a median OS of 8 versus 4.5 months (\( P = 0.019 \)) with erlotinib.
plus sorafenib versus erlotinib plus placebo, respectively. These data suggest a potential benefit for the combination in EGFR-WT tumors, more dependent on other signalling pathways, such as PDGFR, VEGFR or Raf inhibited by sorafenib. Sunitinib is a kinase inhibitor targeting VEGFR-1, -2 and -3, PDGFR alpha and beta, stem-cell factor receptor (KIT), FLT3 and RET that has demonstrated antitumor activity as a single agent in phase II studies, in patients with refractory NSCLC, with RR of 2.1-11.1% [30-31]. In a phase III study, erlotinib 150 mg and blinded sunitinib 37.5 mg or placebo were administered orally once daily every 4-week in patients with recurrent NSCLC [32]. Nine hundred-sixty patients were randomized; the majority of them had a diagnosis of lung adenocarcinoma, with unknown EGFR status. OS (primary endpoint) was similar between the two treatment arms (9.0 versus 8.5 months in erlotinib plus sunitib versus erlotinib, respectively). Patients treated in the combination arm had a modest benefit in terms of PFS (3.6 versus 2.0 months, HR 0.54; 95% CI: 0.36-0.79, P = 0.0015), and ORR (10.6% versus 6.9%, P = 0.0471), respectively.

Negative results were also reported by a phase II study that compared erlotinib plus sunitinib versus erlotinib plus placebo, in patients with metastatic NSCLC pretreated with one or two prior chemotherapy lines [33]. The combination of sunitinib and erlotinib did not improve PFS (2.8 versus 2.0, HR 0.898, P = 0.321), OS (8.2 versus 7.6 months, HR 1.066, P = 0.617) or objective response rates (4.6% versus 3.0%, respectively). A biomarker analysis showed a better PFS for patients with low-tumor PDGFR-alpha RNA in the combination arm, suggesting the relevance of tumor vascular microenvironment when combining angiogenesis and EGFR inhibitors. In both trials rash, diarrhea, fatigue and nausea were more frequent with the combined treatment.

Angiogenesis plus EGFR inhibitors in “EGFR mutated” patients

Several clinical trials evaluated the activity of the dual inhibition of angiogenesis and EGFR in NSCLC patients with EGFR mutation, including combination of erlotinib plus bevacizumab, gefitinib plus bevacizumab, afatinib plus bevacizumab, erlotinib plus ramucirumab (Table 3).

**Bevacizumab and erlotinib**

Retrospective analyses in clinical trials conducted with erlotinib plus bevacizumab in unselected NSCLC patients suggested an advantage of the combination compared with erlotinib as a single agent in patients with EGFR activating mutations. On this basis, a number of phase II-III trials prospectively evaluated the efficacy of the combination in this setting of patients. In the first randomized phase II study (J025567), Seto et al. [34], compared erlotinib plus bevacizumab versus erlotinib in 154 naïve Japanese NSCLC patients with EGFR activating mutations. Erlotinib plus P = 0.0015), but no OS (47 versus 47.4 months, HR 0.81, 95% CI: 0.53-1.23) [35]. A greater benefit from the combination was observed in patients with EGFR exon 19 deletion (median PFS 18 versus 10.3 months, HR 0.41, 95% CI: 0.24-0.72). On the contrary, in patients with EGFR point mutation L858R in exon 21, the benefit seemed to be modest and not clinically significant (HR 0.67, 95% CI: 0.38-1.18). Severe AEs were 91% with erlotinib and bevacizumab and 53% with erlotinib single agent. The most common AEs of any grade were rash, diarrhea, hypertension in the combination group; rash, diarrhea and paronychia in the erlotinib group. These findings were confirmed by the NEJ026 phase III study [36]. In this trial, 112 Japanese patients with EGFR-positive NSCLC were randomized to erlotinib plus bevacizumab and 114 to erlotinib single agent. The results from the preplanned interim analysis showed an improvement in PFS with the combination strategy compared with erlotinib single agent (16.9 compared with 13.3 months, HR 0.605, 95% CI: 0.417-0.877, P = 0.016), with a worse toxicity profile (grade 3-5 AEs in 88% versus 46% of patients, respectively). Moreover, erlotinib plus bevacizumab was associated with a higher frequency of hypertension (46% versus 10%), proteinuria (32% versus 5%), and non pulmonary haemorrhage (26% versus 3%). The BELIEF trial evaluated the activity of first-line erlotinib plus bevacizumab in patients with activating EGFR mutations, according to the expression of T790M resistance mutation [37]. Since the T790M mutation is linked to a high level of signal transducer and activator of transcription 3 (STAT3) protein which up-regulates the VEGF expression, this study was intended to be a proof of concept that adding bevacizumab to erlotinib could improve the treatment of de-novo T790M mutated patients. Among 109 patients treated with erlotinib and bevacizumab, 37 (34%) were T790M positive. The overall median PFS was 13.2 months (95% CI: 10.3-15.5), with a 12 month PFS survival rate of 55% (95% CI: 45-64). The primary end point was met only in T790M-positive patients, with a median PFS of 16 months and a 12 month PFS rate of 68%. Severe AEs were reported in 4.7% of patients included in the safety analysis (including one acute coronary syndrome and a colonic perforation). Inconclusive results were reported by a small phase II trial conducted in U.S. comparing erlotinib plus bevacizumab against erlotinib alone in 88 EGFR mutated patients (75% Caucasian) [38]. The combination failed to result in a significant difference in PFS (17.9 versus 13.5 months, respectively; P = 0.39) and OS (32.4 versus 50.6 months, respectively; P = 0.33). However, these results were affected by the small number of enrolled patients resulting in a low power of the study. The more frequent serious AEs in the combination and erlotinib arms were skin eruption (26% versus 16% of patients), diarrhea (9% versus 13% of patients), hypertension (40% versus 20% of patients), and proteinuria (12% versus 0% of patients).

**Bevacizumab and other EGFR TKIs**

The Okoyama Lung Cancer Study Group 1001 evaluated the activity of the combination of gefitinib and bevacizumab in metastatic NSCLC patients harbouring the EGFR mutation [39]. Forty-two Japanese patients received gefitinib 250 mg/day plus bevacizumab 15 mg/kg every three weeks. Median PFS was 14.4 months and 1-year PFS rate was 56.7% (95% CI: 39.9-70.5), but the primary end point of the study was not met, because the lower limit of the CI reached the 40% threshold. Cutaneous rash, hypertension, proteinuria and diarrhea were the AEs more frequently reported. Negative results were also reported in another Japanese phase II trial that evaluated the activity of gefitinib plus bevacizumab in EGFR mutated patients with metastatic NSCLC cancer, without brain metastases and T790M expression, although the conclusions of this study were invalidated by the very small sample size (16 patients) [40]. A phase II trial (the ABC study) evaluated afatinib plus bevacizumab in metastatic EGFR mutated NSCLC, pretreated with erlotinib or gefitinib [41]. Thirty-two patients were enrolled in the trial; in 14 of them (44%) the T790M expression was detected. Six patients (18.8%, 95% CI: 7.2-36.4%) obtained an objective response. In patients T790M positive the ORR and median
PFS were 14.3% and 6.3 months, while in T790M negative they were 22.2% and 7.1 months, respectively. AEs frequently reported were skin rash and diarrhea. Therefore, the combination seemed to be promising in T790M negative patients who were found to be resistant to other EGFR treatments.

**Ramucirumab and erlotinib**

The Relay study compared ramucirumab plus erlotinib against erlotinib plus placebo in EGFR mutated metastatic NSCLC, without brain metastases [42]. The trial enrolled 449 patients with common EGFR mutations (patients with T790M mutation at baseline were excluded): 224 patients were randomized to erlotinib 150 mg/day plus ramucirumab 10 mg/kg every two weeks, while the remaining 225 patients were randomized to erlotinib plus placebo. The addition of ramucirumab to erlotinib improved PFS (19.4 versus 12.4 months, HR: 0.59, 95% CI: 0.46-0.76, \(P\) < 0.0001). OS data were immature. No difference in the percentage of patients who developed T790M mutation between the two groups was reported. One patient died during the treatment due to an event potentially related to the ramucirumab-erlotinib treatment. In the combination group, a serious AE was reported in 29% of patients, including hypertension (24%) and cutaneous rash (15%). In the control group, the 21% of patients had a serious AE, including hypertransaminasemia (8%) and cutaneous rash (9%). Recently, the combination of erlotinib and ramucirumab has been approved by FDA for the treatment of EGFR mutated naïve patients.

**Discussion and future perspectives**

The combined treatment with angiogenesis and EGFR inhibitors showed contrasting results in patients with advanced NSCLC. In pretreated EGFR wild type patients, bevacizumab plus erlotinib improved RR and PFS in the BeTa trial [19], although the benefit was modest and did not translate into an OS advantage. Similarly, in the maintenance setting, erlotinib plus bevacizumab slightly improved PFS, but not OS. Moreover, the combination strategy was associated with more frequent AEs. In the first-line setting, bevacizumab plus erlotinib was even inferior to chemotherapy in EGFR wild-type patients [25-26], confirming the evidence coming also from the TORCH study that a strategy with an EGFR inhibitor is not recommended in unselected, naive, advanced NSCLC patients [43]. Negative results were also reported with the combination of oral VEGF inhibitors and erlotinib in the second-line treatment of a advanced NSCLC patients with EGFR wild type tumors: in particular, sunitinib plus erlotinib resulted in greater responses and longer PFS, but this benefit was not clinically relevant and it was associated with more toxicity [32]. On the contrary, in EGFR mutated patients the combination of bevacizumab or ramucirumab with erlotinib showed a statistically significant and clinically relevant improvement of PFS [34, 36, 42] and this result led to the approval of these two regimens in the first-line therapy of patients with EGFR mutant NSCLC. No OS benefit was observed in the JO25567 trial [35], while the survival data are not mature for the two phase III trials with bevacizumab (NEJ026) and ramucirumab (RELAY). A meta-analysis of ten studies including 2, 802 participants with advanced NSCLC demonstrated that erlotinib plus bevacizumab failed to improve OS (95% CI: 0.87-1.12, \(P\) = 0.825), PFS (95% CI: 0.63-1.15, \(P\) = 0.297) and objective response rate (95% CI: 0.69-1.67, \(P\) = 0.758), and it had a worse toxicity profile (rash and diarrhea) [44]. However, a subgroup analysis suggested an improvement in overall survival (95% CI: 0.29-0.69, \(P\) < 0.001) for patients with EGFR mutations treated with combination therapy.

A possible explanation of the positive results of bevacizumab plus erlotinib in mutated EGFR patients and, conversely, the lack of a relevant effect of the same combination in EGFR wild type patients could be an improved delivery of erlotinib due to the effect of bevacizumab on tumor vessel physiology: the increased intratumoral concentration of the EGFR TKI could induce a positive effect only in oncogene addicted tumors, being non oncogene addicted tumors less sensitive to EGFR TKIs. However, other mechanisms might be involved in the synergism of anti-VEGF and anti-EGFR drugs. In fact, the EGFR system has been shown to promote the secretion of VEGF and other angiogenic factors in tumor cells [14-15]. Activation of the EGFR also induces the release of angiogenic factors, including VEGF, in mesenchymal stem cells within the tumor microenvironment [45]. Therefore, combination of VEGF and EGFR inhibitors can induce a more significant reduction of angiogenic factors within the tumor. Finally, pre-clinical studies also suggest a possible role of VEGF in the acquired resistance of cancer cells to anti-EGFR agents [46]. Further data on bevacizumab and
erlotinib combination will be soon available from other ongoing clinical studies (Table 4). The Beverly study (ClinicalTrials.gov/NCT02633189) is the first phase III clinical trial that has enrolled Caucasian patients with naïve metastatic NSCLC and activating EGFR mutation [47]. Patients have been randomized in a 1:1 fashion in two arms: erlotinib plus bevacizumab or erlotinib alone. Co-primary end points are investigator and centrally assessed PFS. The trial is powered to detect an HR difference of 0.60 and it has completed the planned enrollment of 160 patients in 2018. Two further randomized phase II clinical trials are ongoing in Taiwanese (the Brilliant trial; ClinicalTrials.gov/NCT02655536) and Korean (the Ava-TA trial; ClinicalTrials.gov/NCT03126799) patients to compare bevacizumab and erlotinib combination versus erlotinib alone in metastatic naïve NSCLC patients harbouring EGFR mutations. Results of these two studies are soon to be released.

Table 4. Ongoing studies

| Trial                  | Phase | Setting                  | Stage          | Patients | Treatment                                      | Primary end points |
|------------------------|-------|--------------------------|----------------|----------|------------------------------------------------|--------------------|
| Beverly trial          | III   | Metastatic, first line   | IV stage       | 200      | Erlotinib + Bevacizumab vs. Erlotinib           | PFS                |
| NCT02633189            |       |                          |                |          |                                                 |                    |
| Brilliant trial        | II    | Metastatic, first line   | IV stage, brain metastases | 109      | Erlotinib + Bevacizumab vs. Erlotinib           | PFS                |
| NCT02655536            |       |                          |                |          |                                                 |                    |

| NCT03126799            |       |                          |                |          |                                                 |                    |
| NCT02803203            | I/II  | Metastatic, first line   | IV stage       | 50       | Osimertinib + Bevacizumab                       | PFS                |
| BOOSTER                | II    | Metastatic, second line  | IV stage, T790M mutated | 155      | Osimertinib + Bevacizumab vs. Osimertinib      | PFS                |
| NCT03133546            |       |                          |                |          |                                                 |                    |
| ACCRU                  | II    | Metastatic, first line   | IV stage, brain metastases | 112      | Osimertinib + Bevacizumab vs. Osimertinib      | PFS                |
| NCT02971501            |       |                          |                |          |                                                 |                    |
| OWONBNSCLCLM NCT04148898 | II  | Metastatic, first line   | IV stage, leptomeningeal metastases | 80       | Osimertinib + Bevacizumab vs. Osimertinib      | ORR and iPFS       |
| NCT04181060            | III   | Metastatic, first line   | IV stage       | 300      | Osimertinib + Bevacizumab vs. Osimertinib      | PFS                |
| NCT03909334            | II    | Metastatic, first line   | IV stage, also in patients with brain metastases | 150      | Osimertinib + Ramucirumab vs. Osimertinib      | PFS                |
| NCT02789345            | I     | Metastatic, first line   | IV stage, T790M mutated | 74       | Osimertinib + Ramucirumab + Necitumab          | DLTs               |

iPFS: intracranial progression-free survival

The major limitation of all these trials is that the control arm (erlotinib) is no longer the standard therapy for advanced NSCLC patients with activating EGFR mutations, due to the superiority of osimertinib over first generation EGFR TKIs demonstrated by the FLAURA trial [13]. On this basis, a number of clinical trials are currently evaluating the feasibility and activity of the combination of osimertinib with bevacizumab or ramucirumab (Table 4) in the first-line setting. A phase I/II trial is currently assessing the feasibility and efficacy of the combination of osimertinib and bevacizumab in EGFR mutated patients (ClinicalTrials.gov/NCT02803203). In the first part of the study, patients will receive bevacizumab 15 mg/kg every three weeks plus osimertinib 40 mg or 80 mg daily; the maximum tolerated dose will be assessed and it will be used in the phase II part of the trial, which has PFS as primary outcome. Estimated study completion is planned for June 2020. A randomized phase II clinical trial (The Booster trial, ClinicalTrials.gov/NCT03133546) is also comparing the combination of bevacizumab and osimertinib against osimertinib alone as second-line therapy in patients already treated with an EGFR inhibitor and a confirmed T790M mutation; the primary outcome will be PFS, while the secondary outcomes will be ORR, OS and AEs; the trial will involve 25 Centers in Europe and Asia. Study completion is awaited for May 2022. A randomized phase II trial (ClinicalTrials.gov/NCT02971501) will determine the efficacy of first-line osimertinib plus bevacizumab against osimertinib alone in previously untreated EGFR mutated patients with brain metastases. Primary endpoint will be PFS, secondary endpoints will be OS, AEs, ORR, intracranial response rate and time to intracranial progression.
Estimated study completion is awaited for July 2020. Another phase II study (ClinicalTrials.gov/NCT04148898) is evaluating the activity of bevacizumab plus osimertinib in EGFR mutated metastatic patients and leptomeningeal disease. Eligible patients will receive osimertinib or osimertinib and bevacizumab. Primary endpoints will be intracranial PFS and ORR; secondary end points will be leptomeningeal disease overall survival (intended to be the survival from the diagnosis of leptomeningeal disease), PFS and the appearance of AEs. Study completion is awaited on July 2021. Finally, a phase III trial (ClinicalTrials.gov/NCT04181060) will compare the efficacy of osimertinib plus bevacizumab against osimertinib alone in untreated metastatic NSCLC with EGFR mutation. Primary outcome measure will be PFS, secondary will be OS. The study will start in June 2020 and results are awaited in September 2025 and should definitively assess the efficacy of osimertinib and bevacizumab combination in naïve NSCLC patients with activating EGFR mutations. Two studies are evaluating the combination of ramucirumab with osimertinib. A phase II study (ClinicalTrials.gov/NCT03909334) will determine the activity of osimertinib plus ramucirumab against osimertinib in previously untreated EGFR mutated metastatic patients; primary endpoint will be PFS, secondary endpoints will be ORR, OS and AEs. Results are awaited for June 2024. A phase I trial (ClinicalTrials.gov/NCT027893459) will assess the safety of ramucirumab or necitumumab plus osimertinib in advanced NSCLC patients with EGFR activating mutations and expression of T790M, in progression after EGFR TKIs. The primary end point will be DLTs; among secondary end points there are PFS and OS; results are awaited for May 2020.

However, despite the relevant benefit in PFS observed in clinical trials, several issues may limit the use of the combinations of angiogenesis inhibitors plus EGFR TKIs in EGFR mutant patients: the need of an intravenous infusion of bevacizumab or ramucirumab with consequent frequent patients admissions in Hospital; the increased incidence of treatment associated AEs compared with EGFR TKIs as single agents; the exclusion of patients with tumors located in central position or at risk of hemorrhage; the frequent exclusion of patients with brain metastases; the increased costs of the combination. The identification of molecular biomarkers that could predict the response to the combination of angiogenesis and EGFR inhibitors, identifying patients which could derive more benefit from this combination, is an important goal of research to optimize the combined use of these agents.

**Abbreviations**

AE: adverse event  
bFGF: beta fibroblast growth factor  
CI: confidence interval  
DLT: dose limiting toxicity  
EB: erlotinib plus bevacizumab  
EGFR: epidermal growth factor receptor  
FGFR: fibroblast growth factor receptors  
Flt-4: FMS-related tyrosine kinase 4  
HER 1: human epidermal growth factor receptor 1  
HR: hazard ratio  
iPFS: intracranial progression-free survival  
KIT: stem cell factor receptor  
KRAS: kirsten rat sarcoma  
NPR: non progression rate  
NSCLC: non-small-cell lung cancer  
ORR: overall response rate  
OS: overall survival  
PDGFR: platelet-derived growth factor receptors
PFS: progression free survival
PGB: cisplatin, gemcitabine and bevacizumab
PR: partial response
RAF: rapidly accelerated fibrosarcoma
RET: rearranged during transfection
RR: response rate
STAT3: signal transducer and activator of transcription 3
TKI: tyrosine kinase inhibitor
VEGF: vascular endothelial growth factor
VEGFR: vascular endothelial growth factor receptor
WT: wild type
