Abstract. A worldwide increase in the \textit{Mycobacterium abscessus} (\textit{M. abscessus}) complex has been observed. Therefore, the aim of the present study was to investigate the diversity of the \textit{rrl} and \textit{erm}(41) genes, both of which are associated with macrolide sensitivity in the \textit{M. abscessus} complex. The current study also examined the efficacy of mass spectrometry as an alternative to molecular testing to classify subspecies of the \textit{M. abscessus} complex. A total of 14 strains of the \textit{M. abscessus} complex were obtained, and based on conventional analyses using housekeeping genes, 57% were determined to be \textit{M. abscessus} subsp. \textit{abscessus}, 43% were \textit{M. abscessus} subsp. \textit{massiliense}, and none were identified as \textit{M. abscessus} subsp. \textit{bolletii}. However, depending on the strain, it was not always possible to distinguish between the subspecies by mass spectrometry. Consequently, PCR products for the \textit{rrl} and \textit{erm}(41) genes were directly sequenced. Overall, 7.1% of the strains were identified to have a \textit{rrl} mutation, and 92.9% carried a T at position 28 of \textit{erm}(41). Results presented here suggest that the principal cause of treatment failure for \textit{M. abscessus} complex infections is inducible macrolide resistance encoded by the \textit{erm}(41) gene. From a strictly pragmatic standpoint, the phenotypic function of a putative \textit{erm}(41) gene is the most important piece of information required by clinicians in order to prescribe an effective treatment. Although PCR amplification of \textit{erm}(41) is not sufficient to differentiate between the \textit{M. abscessus} complex subspecies, PCR can be easily and efficiently used to predict the sensitivity of members of the \textit{M. abscessus} complex to clarithromycin.

Introduction

Recent epidemiology research has revealed a worldwide increase in non-tuberculous mycobacteria (NTM) infections. In Japan in particular, the \textit{Mycobacterium abscessus} (\textit{M. abscessus}) complex is the third most common pathogen in pulmonary diseases caused by NTM, after the \textit{Mycobacterium avium} complex and \textit{Mycobacterium kansasii} (1). The \textit{M. abscessus} complex is categorized as rapidly growing mycobacteria, defined by visible growth within seven days, and is one of the most difficult pathogens to treat. Over the past decade, the \textit{M. abscessus} complex has been subclassified into three new subspecies: \textit{M. abscessus} subsp. \textit{abscessus}, \textit{M. abscessus} subsp. \textit{massiliense} and \textit{M. abscessus} subsp. \textit{bolletii} (2). Macrolides are the key drugs used for the treatment of \textit{M. abscessus} complex infection; however, macrolides are not always effective or in some cases they lose effectiveness during the course of treatment. Acquired macrolide resistance is associated with point mutations in the \textit{rrl} gene, which encodes 23S rRNA (3). An erythromycin ribosomal methylase, encoded by \textit{erm}(41) in the \textit{M. abscessus} complex, confers inducible resistance to macrolides (4). The functionality of the \textit{erm}(41) gene differs depending on the subspecies. Most notably, \textit{M. abscessus} subsp. \textit{massiliense} has been proposed to have an incomplete \textit{erm}(41) gene, which is associated with macrolide sensitivity. In addition, some \textit{M. abscessus} subsp. \textit{abscessus} strains have substitutions in the \textit{erm}(41) gene that also lead to macrolide susceptibility. Thus, it is important to distinguish the three kinds of subspecies and to analyze the sequences of the \textit{rrl} and \textit{erm}(41) genes. Matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF MS) has been used for microbial identification in recent years, and several researchers have attempted to apply this tool to differentiate the subspecies of the \textit{M. abscessus} complex. However, different diagnostic criteria have been used at different institutions and the results of the method are inconsistent (5-10).

Few studies have investigated the ratio of subspecies of the \textit{M. abscessus} complex in Japan, or examined their macrolide resistance genes (11). It is likely that regional differences in the ratios of the subspecies and the clinical features of such isolates may exist. In the present study, we aimed to examine the sequence of the \textit{erm}(41) gene in \textit{M. abscessus} complex
subspecies. We also compared the efficacy of using molecular testing and mass spectrometry to classify subspecies of the *M. abscessus* complex.

**Materials and methods**

**Samples and data collection.** Fourteen strains of the *M. abscessus* complex were obtained from each patient between July 2016 and April 2018 at Showa University Hospital (Tokyo) or at Showa University Fujigaoka Hospital (Yokohama). For reference, one strain of *Mycobacterium fortuitum* (*M. fortuitum*) was collected during the period. All strains were of sputum origin except for one *M. abscessus* complex isolate from a bronchoscopy. Clinical isolates were cultured in mycobacteria growth indicator tubes (MGIT) and in 2% Ogawa solid medium. *M. abscessus* complex and *M. fortuitum* were distinguished by DNA-DNA hybridization. All clinical data were collected from medical records. Official approval for the study was obtained in advance from the Ethics Committee for Research at Showa University (approved numbers 371 and 2016127). Informed consent was waived because of the retrospective nature of the study.

**Molecular testing.** DNA was extracted from mycobacterial clinical isolates using InstaGene matrix (Bio-Rad Laboratories) and stored at -20°C. The amount of DNA extracted ranged from 104 to 452 ng/µl. Primers for nucleic acid amplification were designed as indicated in Table I. PCRs were performed to amplify mutation hot spot regions in the housekeeping genes *hsp65, rpoB* and ITS to classify the strains into the three subspecies using a Mycycler ver.10.65 thermal cycler (Bio-Rad Laboratories). The *rrl* and *erm*(41) genes were also amplified in a similar manner. All PCR assays were carried out in 25-µl volumes containing 200 ng of template DNA, 0.1 units of Taq DNA polymerase (Roche Diagnostics), 25 pmol of each primer, and 10 nmol of dNTPs. Cycling parameters were 30 sec at 95°C, 30 sec at 60°C, and 60 sec at 72°C for 30 cycles. PCR products were separated on a 5% polyacrylamide gel or 1% agarose gel. The gels were stained with ethidium bromide and photographed under UV illumination. The PCR products were purified and were directly sequenced using a BigDye terminator kit and ABI Prism 3130 xl (Applied Biosystems). Sequences could not be obtained by direct sequencing, the PCR products were ligated into a pGEM T easy vector (Promega), which was then used to transform JM109 cells, as reported previously (12). Multiple clones were selected and plasmid DNA was purified from each and sequenced. The reference sequences for each gene were obtained from GenBank (accession numbers CU458796.1: *M. abscessus* subsp. *abscessus*, AP_0145471: *M. abscessus* subsp. *massiliense*).

**Antibiotic susceptibility test.** Minimum inhibitory concentrations (MICs) of amikacin and clarithromycin were determined by the broth microdilution method and were interpreted according to the Clinical and Laboratory Standards Institute document M24-A2 (13). Briefly, an appropriate volume of the culture was transferred into 3 ml of sterilized saline until the turbidity matched that of a 0.5 McFarland standard. A 10 µl aliquot of the suspension was used to inoculate 11 ml of cation-adjusted Mueller-Hinton medium and 100 µl was distributed into each of the 96 well panels. The panels were incubated for 72 h at 30°C, and growth was determined. To test for inducible resistance to clarithromycin, the MICs for clarithromycin were also determined after 7 and 14 days of incubation.

**Mass spectrometry.** Colonies were transferred into microcentrifuge tubes containing 300 µl of sterile deionized water, and the tubes were incubated for 30 min at 95°C. Then samples were mixed with 900 µl of 70% ethanol by vortexing for 1 min. The suspensions were centrifuged at 13,000 rpm for 2 min, and the pellets were dried for 5 min at room temperature and resuspended in 20 µl of 100% acetonitrile with zirconia beads. The mixtures were vortexed for 1 min. The samples were then suspended with 20 µl of 70% formic acid and centrifuged at 13,000 rpm for 2 min. Subsequently, 1 µl of the supernatant from each extract was spotted on a target plate. After drying, 1 µl of matrix solution (saturated α-cyano-4-hydroxycinnamic acid in 47.5% acetonitrile and 2.5% trifluoroacetic acid) was added onto each spot. Mass spectra were obtained on a MALDI Biotyper ver 4.0 configured with Micro flex LT/SH with Mycobacteria Library ver.5.0 (Bruker Daltonik). Spectra were analyzed by Flex Analysis software 3.4 and MBT compass explore ver 4.1 (Bruker Daltonik).

**Statistical analysis.** The significance in each group was evaluated with Fisher's exact test or Pearson's Chi-square test, unpaired student's t-test, and the nonparametric Mann-Whitney test on ranks. P<.05 was considered significant. All analyses were performed using JMP 13.0 software (SAS Institute).

**Results**

**Determination of *M. abscessus* complex subspecies by sequencing housekeeping genes.** The results of sequence analyses of housekeeping genes are shown in Table II. To distinguish the three subspecies, *hsp65, rpoB* and ITS sequences were determined by direct sequencing and compared to reference sequences. The sequences of the *hsp65* genes from eight strains were consistent with the reference sequence from *M. abscessus* subsp. *abscessus*, while those from six strains were consistent with the reference sequence from *M. abscessus* subsp. *massiliense*, with the exception of one strain (no. 9626), which had a change at position 280T>A. High heterogeneity of *rpoB* in the *M. abscessus* complex has been reported (14). The *rpoB* genes from eight strains were identical to the reference gene from *M. abscessus* subsp. *abscessus*, while a 37C>T change was present in two strains (no. 71470 and no. 9614), and two changes (52C>T and 391C>T) were found in another strain (no. 8548). Six strains had *rpoB* sequences identical to the reference sequence from *M. abscessus* subsp. *massiliense*, with the exception of one substitution, 316T>C that was detected in four strains (nos. 74369, 77944, 9626, and 9388). No amino acid changes resulted from these nucleotide sequence differences. Together, eight strains were identified as *M. abscessus* subsp. *abscessus*, and six strains as *M. abscessus* subsp. *massiliense*. The results of sequence analyses of the ITS region were consistent with these findings. However, a novel insertion sequence (180_181GTTGT) was found in one strain of *M. abscessus* subsp. *abscessus* (no. 71740).
Patients and characteristics. As mentioned above, results were obtained for all patients, 57% (8 of 14) of whom were infected with *M. abscessus* subsp. *abscessus*, and 43% (6 of 14) of whom were infected with *M. abscessus* subsp. *massiliense*. None were infected with *M. abscessus* subsp. *bolletii*. Table III shows the patient characteristics. There were seven males and seven females whose ages at diagnosis ranged from 30 to 83 years: Thirteen were Japanese and one was Indian. According to the guidelines published by the American Thoracic Society/Infectious Diseases Society of America (15), all patients were newly diagnosed with *M. abscessus* complex pulmonary disease, based on at least two positive culture results derived from pulmonary samples. As shown in Table III, there was no significant association of the subspecies with age, body-mass index, sex, smoking history, radiological findings, hemoptysis, sputum smear, or C-reactive protein.

Gene status of rrl and erm(41). Sequence differences identified in the rrl and erm(41) genes are summarized in Table IV. In the rrl gene, a A>G change was detected at position 2059 in one strain (no. 8006), but no other alterations were found. As for the erm(41) gene, nucleotides at positions 64_65 and 159_432 were deleted in strains of *M. abscessus* subsp. *massiliense*, compared to the *M. abscessus* subsp. *abscessus* strains. Eight substitutions were found in the *M. abscessus* subsp. *abscessus* isolates, whereas no substitutions were found in the strains of *M. abscessus* subsp. *massiliense*. In those isolates of *M. abscessus* subsp. *abscessus*, 28T>C, 238A>G and 419C>T substitutions were responsible for the amino-acid changes W10R, I80V and P140L, respectively. As shown in Fig. 1, the sizes of the PCR products amplified from the *erm(41)* genes were consistent with sequencing results (673 base pairs for *M. abscessus* subsp. *abscessus*, and 397 base pairs for *M. abscessus* subsp. *massiliense*), and identifications based on the size of the *erm(41)* gene were consistent with those based on *hsp65*, *rpoB* and ITS sequences.

Antimicrobial sensitivity. Table V shows the antibiotic susceptibility of the *M. abscessus* strains to amikacin and clarithromycin. The MICs of amikacin ranged from 2 to 16 µg/ml, which indicated that all strains were sensitive. There was no difference in the MICs between the two subspecies. *M. abscessus* subsp. *abscessus* isolates were sensitive to clarithromycin on day 3, but the MICs were significantly higher on day 14 with one exception (no. 9944). In contrast, the strains of *M. abscessus* subsp. *massiliense* were susceptible to clarithromycin on days 3 through 14, except for one strain (no. 8006), which showed resistance from the start. Strain no. 9626 was sensitive early in the testing period, but the MIC was about 4-fold higher on day 14.

MALDI-TOF MS analysis. The details of mass spectra are shown in Figs. 2 and 3. Out of the 14 isolates, 11 were analyzed using MALDI-TOF MS. For reference, one clinical isolate of *M. fortuitum* was simultaneously analyzed in a similar manner. The 11 strains were identified as *M. abscessus* complex (score range, 1.66 to 2.14) and were correctly differentiated from the strain of *M. fortuitum* (Fig. S1). As shown in Fig. 2, the representative spectra of *M. abscessus* complex subspecies were similar at a laser frequency of 50 Hz across 2,000 to 12,000 m/z. When magnifying the spectrum (Fig. 3), distinctive peaks reported previously (8,10) were detected in some cases, but not in all samples. More specifically, peaks around 4390, 7639, 8781 and 9473 m/z for *M. abscessus* subsp. *abscessus* and peaks around 4385, 7669, and 8767 m/z for *M. abscessus* subsp. *massiliense* were found. However, each baseline was unstable and the peaks were wide and low for these strains. Moreover, discriminating peaks were mostly of low intensity or were overlapping. Thus, detection of clearly identifiable differences between strains of different subspecies was extremely difficult. Overall, it was possible to discriminate between *M. abscessus* subsp. *abscessus* and *M. abscessus* subsp. *massiliense* by using mass spectra only in some cases.

Discussion

In the current study, *M. abscessus* complex isolates obtained from patients treated at our institutes located in the Tokyo-Yokohama area were analyzed. Overall, 57% (8 of 14) of the isolates were identified as *M. abscessus* subsp. *abscessus*, 43% (6 of 14) as *M. abscessus* subsp. *massiliense*, and none as *M. abscessus* subsp. *bolletii*. It has been reported

Bold letters demonstrate base-pair changes compared to sequences in CU458896. ins, insertion. <sup>a</sup>Nucleotide positions are based on the *M. abscessus* subsp. *massiliense* sequence (accession no. AB548601). <sup>b</sup>Nucleotide positions are based on the *M. abscessus* subsp. *massiliense* sequence (accession no. AB548600). <sup>c</sup>Nucleotide positions are based on the *M. abscessus* subsp. *massiliense* sequence (accession no. AB548603). <sup>d</sup>CU458896 (ATCC19977) is a reference sequence for *M. abscessus* subsp. *Abscessus*. <sup>e</sup>AP014547 (JCM15300) is a reference sequence for *M. abscessus* subsp. *massiliense*.
that *M. abscessus* subsp. *abscessus* is the most predominant subspecies of the complex followed by *M. abscessus* subsp. *massiliense*, and that *M. abscessus* subsp. *bolletii* is quite rare, ranging from 0-3% in Japan (11,16-19). There were no significant differences in clinical features between *M. abscessus* subsp. *abscessus* and *M. abscessus* subsp. *massiliense*. Clinical characteristics of the *M. abscessus* complex did not help us to distinguish those subspecies, which is consistent with findings reported in the literature (11,20).

The proportion of the *M. abscessus* complex subspecies varies depending on the region from which they are isolated. Compared to Western Europe, the prevalence of *M. abscessus* subsp. *bolletii* is lower in East Asian countries (21-24). Although, *M. abscessus* subsp. *abscessus* is the most predominant subspecies of the complex in most parts of the world, some studies have reported that *M. abscessus* subsp. *massiliense* is more abundant than *M. abscessus* subsp. *abscessus* in some parts of East Asia such as Taiwan and Korea (5,21,22,25). Actually whole-genome sequencing analyses revealed genetic distinctions between *M. abscessus* subsp. *abscessus* isolates in Asia and Western Europe (26), suggesting that the phylogenetic diversity correlates with the regional ratio of the subspecies.

The current commercial system for NTM differentiation in Japan consists of the DNA-DNA hybridization method, which is unable to differentiate subspecies of the *M. abscessus* complex. The three subspecies also cannot be distinguished by 16S rRNA gene sequencing, which is commonly used for bacterial taxonomy in academic research, because the 16S rRNA genes in the three subspecies are 100% identical (27). The differentiation requires sequencing of several housekeeping genes, which is not easy to accomplish in most mycobacteriology laboratories. Hence, these three subspecies have not been distinguished in hospital laboratories. Sequencing of a single target gene may lead to inaccurate identification of closely related subspecies; however, multilocus sequence analyses of the *M. abscessus* complex have been described using hsp65, rpoB, ITS, *gyrB*, dnaA, recA and secA (28). Although some other methods based on technology developed by multilocus sequence analyses have been designed, such as variable-number tandem repeat analysis (18,19,29,30) and multiplex PCR (17,31), those methods are complicated. In the present study, subspecies of the *M. abscessus* complex were differentiated based on partial sequences of the hsp65 and *rpoB* genes, and results of ITS sequencing were also consistent in differentiating the two subspecies. In a subset of *M. abscessus* complex isolates, a hybrid genetic pattern for the hsp65 and *rpoB* genes has been reported (32,33), presumably the result of horizontal gene transfer between the subspecies. In such cases ITS gene analysis was essential to identify the subspecies. Sequencing of at least three housekeeping genes should therefore be carried out for subspecies identification.

Numerous institutions are seeking an alternative way to distinguish the *M. abscessus* subspecies in clinical practice. MALDI-TOF MS has been evaluated for the identification of microorganisms including mycobacteria. However in this study, it was not possible to distinguish between the *M. abscessus* subspecies of all isolates by MALDI-TOF MS. Although several institutes have reported the efficacy of MALDI-TOF MS in differentiating the three subspecies of the *M. abscessus* complex (5-10), methods for sample

<sup>a</sup>Numbering system for the rrl gene from *Escherichia coli*; <sup>b</sup>Numbering system for the erm(41) gene, with the GTG start codon as 1; <sup>c</sup>CU458896 (ATCC19977) is a reference sequence for *M. abscessus* subsp. *Abscessus*; <sup>d</sup>AP014547 (JCM15300) is a reference sequence for *M. abscessus* subsp. *Massiliense*; <sup>e</sup>T to C transition at position 28 (28T>C) leading to a Trp>Arg amino acid change at codon 10; <sup>f</sup>A to G transition at position 238 (238A>G) leading to a Ile>Val amino acid change at codon 80; <sup>g</sup>C to T transition at position 419 (419C>T) leading to a Pro>Leu amino acid change at codon 140.
preparation and analysis, and diagnostic criteria have not been standardized. When defining the range from 2,000 to 20,000 m/z, ribosomal protein accounts for 50 to 70% of the peptide detected by MALDI-TOF MS. Thus, it is easy to distinguish between species that contain diverse ribosomal proteins. In fact, the current study revealed obvious differences between M. fortuitum and the M. abscessus complex by mass spectra (Fig. S1). However, the mass spectrometry peaks may be affected by variations in culture media formulations, duration of growth, and other conditions. The utility of MGIT liquid medium (10), 5% sheep blood agar (6), Middlebrook 7H11 (7), and Lowenstein-Jensen agar (9) have been reported for MALDI-TOF MS. In the present study, samples were prepared from colonies incubated on 2% Ogawa solid medium. Thus, the diagnostic criteria for MALDI-TOF analysis differ depending on the laboratory carrying out the analyses. Since there are few differences in the ribosomal proteins between the M. abscessus complex subspecies, and the sample preparation for mass spectra is even affected by climate, the procedure is often poorly reproducible. Considerable effort would be necessary to optimize and standardize a protocol to obtain reproducible mass spectrometry results for differentiating the M. abscessus complex subspecies. A proteomics study revealed specific immunogenic proteins in the M. abscessus complex; therefore, the subspecies may be differentiated using immunoassays (34).

Mutations in rrl gene confer acquired resistance and nucleotide T28 of erm(41) is associated with inducible resistance. Since most of the alterations identified in this study were in the erm(41) gene (92.9%; 13 of 14 isolates) rather than the rrl gene (7.1%;1 of 14), we concluded that the main cause of treatment failure for M. abscessus complex infections was inducible resistance encoded by the erm(41) gene. One strain of M. abscessus subsp. massiliense (no. 8006) harboring a point mutation 2059A>G in the rrl gene showed resistance to clarithromycin from day 3 through day 14 (MIC > 128 µg/ml). The presence of rrl mutations was reported in up to 30% of newly isolated strains in East Asia (16,35), whereas no rrl mutations were identified at the time of diagnosis in Spain (36). It has been reported that mutations in the rrl gene rapidly accumulate following clarithromycin use in monotherapy (3). Conversely, several studies have reported on acquired resistance due to rrl mutations in the absence of any macrolide exposure (16,37). However, an in vitro study reported that rrl mutations at position 2058 or 2059 were observed during incubation with clarithromycin (38). In East Asia, low dose macrolides are often administered for prolonged periods to treat chronic respiratory disorders, such as diffuse panbronchiolitis, to stimulate an immunomodulatory effect (39). Hence, careful attention is needed when prescribing macrolides to patients initially diagnosed with pulmonary disease caused by M. abscessus complex. One strain of M. abscessus subsp. abscessus (no. 9944) carried a substitution at position 28T>C in the erm(41) gene, which resulted in a low MIC value for clarithromycin. Other strains that harbored amino acid substitutions at I80V (238A>G) or P140L (419C>T) showed inducible resistance. These data are in agreement with previous reports (4,37) suggesting that the 5’ end of the erm(41) gene is a key region because this region is also predicted to carry a second open reading frame encoding a leader peptide that regulates expression of the erm(41) gene itself (4). In M. abscessus subsp. massiliense, two base deletions (61_62del) have been commonly detected, in addition to longer deletions (159_432del), which are consistent with the findings of the present study. Strains of M. abscessus subsp. abscessus harboring a C>T substitution at position 19, resulting in a stop

Figure 1. Representative PCR products for the erm(41) gene. The amplified products from M. abscessus subsp. abscessus strains (no. 9016, no. 8377, no. 9944 and no. 9854) were 673 bp in length, whereas those from M. abscessus subsp. massiliense strains (no. 9835 and no. 9626) were 397 bp in length. Far left lane, DNA size standard; Lane 1, no. 8377; Lane 2, 9016; Lane 3, 9626; Lane 4, 9944; Lane 5, 9835; Lane 6, 9854.

| *M. abscessus subsp. massiliense* | 74369       | 0.25  | 0.25  | 0.25  |        |
|                              | 9835        | ≤0.06 | ≤0.06 | ≤0.06 |        |
|                              | 77944       | ≤0.06 | ≤0.06 | ≤0.06 |        |
|                              | 9626        | 0.125 | 0.25  | 0.5   |        |
|                              | 9388        | ≤0.06 | ≤0.06 | ≤0.06 |        |
|                              | 8006        | >128  | >128  | >128  |        |

MIC, minimum inhibitory concentration.

Figure 2. Representative MALDI-TOF spectra of *M. abscessus* subsp. *abscessus* and *M. abscessus* subsp. *massiliense* (2,000-12,000 m/z). MALDI-TOF, Matrix-assisted laser desorption ionization-time of flight mass spectrometry.

codon (R7stop), have been previously identified in the findings of a case report (40). The data also highlight the importance of the 5' end of the *erm*(41) gene. With rare exceptions, such as the presence of a full-length *erm*(41) gene (41,42), *M. abscessus* subsp. *massiliense* is generally not associated with inducible macrolide resistance because most strains harbor a truncated *erm*(41) gene (4,21,43). Interestingly, in the present study, one strain (no. 9626) showed a low initial MIC but the MIC
increased 4-fold by 14 days. This observation suggests that mechanisms not involving *erm*(41) can cause inducible resistance. No strains that simultaneously harbored both a *rrl* mutation and nucleotide T28 in *erm*(41) were detected in this study; however, numerous studies have revealed that both resistance mechanisms can occur concurrently (36, 38), and that a functional *erm*(41) gene does not exclude selection for *rrl* mutations (44). Transcriptome analysis of *M. abscessus* complex revealed the presence of several novel open reading frames, which could be activated by stressful conditions, such as hypoxia, to persist (45). Therefore, in addition to antimicrobial resistance genes, pathogenetic gene alterations should also be investigated in the future.

As described above, the two subspecies of the *M. abscessus* complex were found, which is consistent with the results of other studies showing the predominance of *M. abscessus subsp. abscessus* and *M. abscessus subsp. massiliense* in East Asia (11,16,21,24). Data from the current study indicate that the principal difference between the two subspecies was the size of the *erm*(41) gene. Several studies have revealed the presence of a complete *erm*(41) gene in *M. abscessus subsp. massiliense* and *M. abscessus subsp. massiliense* in East Asia (11,16,21,24). Data from the current study indicate that the principal difference between the two subspecies was the size of the *erm*(41) gene. Several studies have revealed the presence of a complete *erm*(41) gene in *M. abscessus subsp. massiliense* and a truncated *erm*(41) gene in *M. abscessus subsp. massiliense* (36), suggesting that *M. abscessus* subsp. *massiliense* acquired a full-length *erm*(41) gene by horizontal transfer from *M. abscessus subsp. abscessus* or *M. abscessus subsp. abscessus*. Additionally, a change at position 28T>C has been reported in *M. abscessus subsp. bolletii* (21)

![Figure 3. Eight peaks differentiate the two *M. abscessus* complex subspecies. The diagram shows the relative intensity (%) against the mass-to-charge ratio values of the discriminating peak regions of MALDI-TOF averaged mass spectral profiles for each subspecies. Acknowledgements

The authors would like to thank Mr. Sadahiro Ichimura and Mr. Hidetoshi Yamamoto (BML Inc., Saitama, Japan) for their microbiological techniques and Ms. Azumi Fujinaga (Bruker Japan K.K., Yokohama, Japan) for help with the mass spectra analysis.

Funding

This work was supported by Grant-in-Aid for Scientific Research(C) (grant no. 17K09021).

Availability of data and materials

The datasets used and/or analyzed during the current study are available from the corresponding author on reasonable request.

Authors’ contributions

AM, FY, TF, YY and YS examined and cared for the patients. AM, FY, TF, YY, YS and KF developed the concept, designed the experiments and analyzed the data. AM wrote the manuscript with contributions from all authors, who commented on it at all stages.

Ethics approval and consent to participate

Official approval for the study was obtained in advance from the Ethics Committee for Research at Showa University (approval nos. 371 and 2016127). Informed consent was waived due to the retrospective nature of the study.

Patient consent for publication

Not applicable.

Competing interests

The authors declare that they have no competing interests.
