Abstract

The finetuning of pretrained transformer-based language generation models are typically conducted in an end-to-end manner, where the model learns to attend to relevant parts of the input by itself. However, there does not exist a mechanism to directly control the model’s focus. This work aims to develop a control mechanism by which a user can select spans of context as “highlights” for the model to focus on, and generate relevant output. To achieve this goal, we augment a pretrained model with trainable “focus vectors” that are directly applied to the model’s embeddings, while the model itself is kept fixed. These vectors, trained on automatic annotations derived from attribution methods, act as indicators for context importance. We test our approach on two core generation tasks: dialogue response generation and abstractive summarization. We also collect evaluation data where the highlight-generation pairs are annotated by humans. Our experiments show that the trained focus vectors are effective in steering the model to generate outputs that are relevant to user-selected highlights.

1 Introduction

Transformer-based models pretrained on large-scale text data have become the dominant paradigm for natural language generation (NLG) tasks (Roller et al., 2020; Lewis et al., 2019; Raffel et al., 2020). The attention module (Bahdanau et al., 2016; Vaswani et al., 2017), which aggregates information via a weighted average over word-level embeddings, plays a vital role in these models. The attention mechanism serves two major purposes: (1) It captures linguistic phenomena in the input (Clark et al., 2019; Kovaleva et al., 2019; Kobayashi et al., 2020); (2) It helps the model focus on relevant portions of the input (e.g., alignment in machine translation (Bahdanau et al., 2016) and abstractive summarization (Rush et al., 2015)).

The attention module is particularly useful as it does not require any explicit supervision: the model learns to attend to relevant parts of the input by itself through end-to-end training. However, this property makes it difficult to explicitly control the model’s focus. If the model happens to put focus on some span of context that the user thinks is not so important, we currently do not have a mechanism to correct it. This is especially sub-optimal in some NLG applications involving a relatively long input such as dialogue or summarization: focusing on different spans of the input could result in completely different generations (illustrated in Figure 1). It would be attractive to give the user an option to control the model’s focus.

In this work, we aim to develop a mechanism to steer the model to generate output relevant to some user-specified input spans (which we term as highlights). This goal, however, brings about significant challenges. For one, many popular NLG datasets are collected in an end-to-end manner, i.e., without annotations of which spans of input are relevant.

To avoid confusion, our goal is not about controlling the attention modules inside the model, instead, we care about the actual generation.
most relevant to the reference target. It would also be ideal for the proposed approach to be compatible with existing pretrained transformer models, as retraining such models is often costly.

In this work, we propose an focus vector framework to address the challenges outlined above. Our contributions are as follows:

• To control the model’s focus, we augment the pretrained model with trainable focus vectors which are directly applied to the encoder embeddings. The model itself is kept fixed, and no further changes to the model architecture is needed.

• The training of focus vectors does not require additional annotations. We utilize attribution methods to derive automatic highlight annotations from existing end-to-end training data.

• For principled evaluation and future work in this direction, we collect and release human evaluation data where the highlight-generation pairs are annotated by humans.

• We test our approach on two core NLG tasks: dialogue response generation and abstractive summarization. Experiments show that the trained focus vectors are effective in steering the model to generate a relevant output given the selected highlights.

2 Model Formulation

We assume the target model is a standard pretrained transformer encoder-decoder model (Vaswani et al., 2017) that has already been finetuned on end-to-end task-specific data (e.g., dialogue or summarization) with the standard negative log-likelihood (NLL) loss. Our goal is to establish a control mechanism whereby the user can highlight several spans of the input, and the model is supposed to generate outputs relevant to the highlighted text. Crucially, this mechanism should not change the base model, in order to allow the user to default back to the original model if desired.

We begin by establishing notation. We denote the end-to-end training data by \( \{x, y\} \), where \( x = \{x_1, ..., x_n\} \) refers to the input token sequence, and \( y \) refers to the corresponding reference target token sequence. During evaluation, some spans of the input \( x \) will be highlighted, and we use a binary indicator \( c_i \) to indicate whether the \( i^{th} \) input token is to be highlighted during generation. In this work we only consider a set of complete sentences as a valid highlight span. This design choice is mainly for convenience during our human-annotated evaluation data collection, and our framework can readily be generalized to phrase-level highlights.

Suppose the encoder model is composed of \( L \) transformer layers. We denote the \( d \)-dimensional output embedding of the \( i^{th} \) position on the \( l^{th} \) encoder layer by \( h_i^l \). We use \( \{h_i^l\} \) to denote the input embeddings. Each decoder layer performs multi-head cross-attention on the outputs of the encoder, where the attention weight computation for the \( h^{th} \) head on the \( l^{th} \) decoder layer is formulated as below:

\[
\alpha_{i,j}^{h,l} = \text{softmax}_{i \in \{1...n\}} \left( \frac{k(h_i^l) \cdot q_j^{h,l}}{\sqrt{d}} \right).
\]

Here \( k(\cdot) \) is a linear transform, and \( \alpha_{i,j} \) is the attention weight assigned to encoder output \( h_i^l \), for the \( j^{th} \) position decoder query vector \( q_j \). We use \( P_M(y|x) \) to denote the probability assigned to \( y \) given input \( x \) by the original target model. For more details of the transformer encoder-decoder architecture, we refer readers to Vaswani et al. (2017).

Our proposed framework involves two stages. We first obtain automatic highlight annotations using attribution methods. Then, these annotations are used to train the focus vectors. In the next section, we review the attribution methods.

2.1 Attribution Methods

Many popular NLG datasets are collected end-to-end, i.e., without annotations of which spans of input are most relevant to the reference target. To obtain these annotations for focus vector training, we make use of existing attribution methods.

Attribution methods (Baehrens et al., 2010; Simonyan et al., 2014; Shrikumar et al., 2017; Adebayo et al., 2018; Sundararajan et al., 2017), also known as saliency maps, attribute the prediction of a (potentially black-box) model to its input features. It thus fits our need to extract relevant spans in the input given the reference target. Most saliency methods are originally designed for image classification, where an importance score is assigned for each dimension of the input feature. Therefore, slight modifications (e.g., dot-product with the word embeddings) are needed to apply them to language data (Ding and Koehn, 2021; Denil et al., 2014).
We implement and compare several popular attribution methods, which compute the attribution score for a given sentence \( S \) (denoting the set of token indexes in the sentence) in the input \( x \) for the target \( y \) and model \( P_M \).

**Leave-one-out (LOO)** We replace the tokens in \( S \) by the \(<pad>\) token, and compute the difference in NLL:

\[
A(S) = \log P_M(y|x) - \log P_M(y|x_{S\text{-padded}}).
\]  

(2)

LOO is also referred to as an occlusion-based method (Zeiler and Fergus, 2014; Li et al., 2016b) in the literature.

**Attention-weight** We sum up the attention weights assigned to tokens in \( S \) for all attention heads across all decoder layers:

\[
A(S) = \sum_{i \in S} \sum_{j,h,l} \alpha_{i,j}^h.
\]  

(3)

**Grad-norm** We sum the norm of gradient for the input word embeddings in \( S \):

\[
A(S) = \sum_{i \in S} ||\nabla h_i^0 \log P_M(y|x)||_2.
\]  

(4)

**Grad-input-product** Instead of taking vector norm, we compute the dot-product between the input embedding and its gradient:

\[
A(S) = \sum_{i \in S} \left( \nabla h_i^0 \log P_M(y|x) \right) \cdot h_i^0.
\]  

(5)

While more sophisticated attribution method have been proposed in the literature (Lei et al., 2016; Sundararajan et al., 2017; Bastings et al., 2019), we mainly experiment with the methods listed above due to their simplicity and popularity. Attribution methods have been used for interpreting black-box models—applying them to derive labels that can further be used to control the focus of a model has to our knowledge not been explored before.

Which attribution method best reflects the model’s inner working is still an active research area (Ding and Koehn, 2021; Adebayo et al., 2018). The present work is primarily concerned with how well the attribution scores align with human-annotated highlights. In our experiments, we find that leave-one-out (LOO) has the best correlation on the human-annotated development set (Table 1, details given in Section 3). We therefore adopt LOO to derive the automatic highlight annotations.

More specifically, for the input-output pairs in the training set, we sort the LOO attribution scores of the sentences in the input from large to small, and mark the tokens in the first few sentences (the exact number varies by task) as highlights. We denote the highlight labels obtained from this automatic procedure by a binary indicator variables \( c^\text{attr} = \{c^\text{attr}_1, \ldots, c^\text{attr}_n\} \), which will be used to train the focus vectors.

### 2.2 Focus Vectors

To control the model’s focus, we introduce a set of \( d \)-dimensional vectors \( \theta \), named *focus vectors*. They are designed to act as indicators for the model, designating which parts of the input to focus on. We now assume the training set contains \( \{x, c^\text{attr}, y\} \) triples, where \( c^\text{attr} \) is obtained from the attribution method from the previous section. Focus vectors modify the forward pass of the encoder model by applying a simple transformation \( f \) on the output embeddings of each layer (including the input layer):

\[
f(h_i) = \begin{cases} 
  h_i^0 \odot \theta^\text{scale-focus} + \theta^\text{bias-focus}, & \text{if } c^\text{attr}_i = 1 \\
  h_i^0 \odot \theta^\text{scale-nonfocus} + \theta^\text{bias-nonfocus}, & \text{if } c^\text{attr}_i = 0 
\end{cases}
\]  

(6)

We provide an illustration in Figure 2. The total number of parameters introduced by the focus vectors is therefore \( 4 \times (L+1) \times d \), which is negligible in comparison to the large number of parameters of the fixed transformer model. We note that as the focus vectors operate directly on the encoder embeddings, it does not require an explicit attention module to exist in the model and is therefore applicable to non-attentional architectures such as LSTMs (Huang et al., 2015).

We train the focus vectors using the standard NLL loss with stochastic gradient descent (SGD):

\[
\mathcal{L}(x, y, c^\text{attr}; \theta) = -\log P_{\text{focus}}(y|x, c^\text{attr}),
\]  

(7)
We test our method on two NLG tasks: dialogue and summarization. To save space, we defer details and statistics of the datasets to Appendix A.

Table 1: Top-1 precision (%) of different attribution methods on the human-labeled development set.

| Attribution Method   | PersonaChat P@1(%) | CNN/Dailymail P@1(%) |
|----------------------|--------------------|-----------------------|
|                      | 29.18              | 40.31                 |
| grad-norm            | 54.00              | 43.87                 |
| grad-input-product   | 44.05              | 32.60                 |
| leave-one-out         | 62.31              | 64.43                 |

where $P_{\text{focus}}(\cdot | x, e^{\text{attr}})$ denotes the distribution over the output after the focus vectors are applied. We re-iterate that during training of the focus vectors, the transformer model is kept fixed. This allows the user to default back to the pretrained model (i.e., without applying the focus vectors), if the user prefers not to specify any highlights.

Readers may wonder what is the difference between our approach and standard end-to-end training, as both cases use the same $x, y$ pairs. This is related to our key assumption that different focus of the input lead to different generations, and the fact that $e^{\text{attr}}$ is the relevant span for $y$ in the ideal case. Therefore, the focus vectors have the opportunity to give information about which span is more relevant to $y$, before the model observes $y$ on the decoder side. To reduce the loss $- \log P_{\text{focus}}(y | x, e^{\text{attr}})$, the focus vectors need to steer the model’s focus towards the spans marked by $e^{\text{attr}}$.

At test time, the user will highlight several sentences in the input which we denote by $e^{\text{user}}$. We apply the trained focus vector according to Equation 6, and decode the output from $P_{\text{focus}}(\cdot | x, e^{\text{user}})$.

### 3 Evaluation Data Collection

We test our method on two NLG tasks: dialogue response generation and abstractive summarization. For the dialogue task, we adopt the PersonaChat dataset (Zhang et al., 2018). It is an open domain multi-turn chit-chat dataset, where two participants are required to get to know each other by chatting naturally. Each of them is given a persona: several pieces of personal information such as “I major in Computer Science”, serving as background information. The participants are required to reflect their assigned persona in the conversation. For summarization, we adopt the CNN/Dailymail dataset (Hermann et al., 2015; Nallapati et al., 2016), which is a standard dataset for end-to-end abstractive summarization. To save space, we defer details and statistics of the datasets to Appendix A.

Both PersonaChat and CNN/Dailymail are created end-to-end and do not contain annotated highlight spans. For principled evaluation, we utilize the Amazon Mechanical Turk (AMT) platform to collect evaluation sets where the highlight-generation pairs are annotated by humans.

For PersonaChat, each turker\(^2\) is shown a dialogue history and the corresponding persona of the speaker. The dialogue history is randomly selected from the original test set of PersonaChat. Then the turker is required to choose 1-3 sentences as highlights (for example, one sentence in persona, and one sentence in dialogue history), and write down a dialogue response that not only continues the current dialogue, but also is relevant to the chosen highlights. Finally, we ask the turker to repeat the above process, but select a different set of highlights and provide another response. After a few preliminary trials and modifications to our instructions / rewards, we find that turkers comply nicely with our instructions and provide high-quality highlight-response pairs.

For CNN/Dailymail however, we first found that turkers had difficulty writing a high-quality summary for a given news article, with many turkers giving random responses even after we increased the reward. This is perhaps unsurprising given that writing a good summary is challenging and the reference summaries are written by experts. After a few disappointing iterations, we turn to a compromise: we directly provide the turkers with the reference summary, and only ask them to select 2-5 relevant sentences in the article. This simplifies the task, and we are able to collect high-quality labels. This compromise is not ideal, as it reverses the order of highlighting and generation. However, we find that in most cases, the reference summaries in CNN/Dailymail are well covered by several “key” sentences in the article, which are highlighted by the turkers. Therefore, we believe this compromise does not hurt the soundness of our evaluation.

In order to ensure high data quality for both dialogue and summarization, we design a qualification test that turkers need to pass before conducting the actual tasks. Several automatic checks and a minimal time limit are added in the scripts to prevent trivial answers. We also manually monitor the incoming submissions, and ban misbehaving turkers and discard their submissions. More details about our AMT setup are provided in Appendix B.

Our final collected datasets include 3,902 highlight-generation pairs for PersonaChat, and

\(^2\)We recruit turkers located in the U.S.
4,159 pairs for CNN/Dailymail. They are randomly split 50/50 into dev/test sets. We include a number of samples of our collected data in the supplementary materials. Our code and the collected dataset will be released in https://github.com/Question406/LearningToFocus.3 We hope that this evaluation data could facilitate future research in this direction.

**Comparison of Attribution Methods** We use the collected highlight-generation pairs in the dev set to compare which attribution method aligns best with human-annotated highlights. In particular, we compute the top-one precision of the sentence ranked highest by the attribution method. The result is shown in Table 1. We find that for both PersonaChat and CNN/Dailymail, LOO has the best alignment. We therefore use LOO to obtain automatic annotations for focus vector training. Interestingly, we observe low alignment between attention weight-derived attribution scores and human judgment, which indicates that controlling model generations via intervening on the attention distributions may not optimal. Finally, we note that this result does not mean LOO is the “best” attribution method, as attribution method is supposed to reflect the model’s inner working, instead of a human’s.

**4 Experiments**

**4.1 Experiment Setting and Baselines**

We use Blenderbot (Roller et al., 2020) as the base model for PersonaChat and BART (Lewis et al., 2019) for CNN/Dailymail, both of which are standard encoder-decoder transformer models. Our code is based on the transformers library (Wolf et al., 2020). We load the pretrained weights from facebook/blenderbot-400M-distill and facebook/bart-base. Blenderbot has 2 encoder layers and 12 decoder layers, while BART has 6 encoder layers and 12 decoder layers. To help Blenderbot cope with long dialogue context in PersonaChat, we extend its maximum position embedding index from 128 to 256. We use beam-search for decoding, where we follow the recommended configuration (Roller et al., 2020; Lewis et al., 2019) and use a beam size of 10 for Blenderbot and a beam size of 4 for BART.

For both tasks, we first finetune the base model on the original training set in the standard end-to-end manner. The model is then fixed and used to obtain automatic labels \(e^{\text{attr}}\) with the LOO attribution method on the same training set. For each training sample, we select the top-\(k\) sentences in the input ranked by LOO. Since we do not know the best value for \(k\), we set it to be a random number from 1 to 3 for PersonaChat, and from 2 to 5 for CNN/Dailymail.

While the highlight labels in the training set used to train focus vectors are derived automatically, we use the human-labeled dev set for hyperparameter tuning. This is to facilitate fair comparison with other baseline approaches which also utilize the human-labeled dev set. In our ablation study, we will show that this dependence on human-labeled dev set is not crucial for our approach to achieve strong performance. We perform a grid search over learning rate with \(\{1, 3, 5\} \times \{1e^{-4}, 1e^{-3}, 1e^{-2}, 1e^{-1}\}\). The Adam optimizer (Kingma and Ba, 2014) is used with \(\beta_1 = 0.9, \beta_2 = 0.999\), and a L2 decay weight of 0.01. For both tasks, we set the mini-batch size to be 16.

We compare the proposed focus-vector approach with several baselines:

**Vanilla:** The vanilla model, without any modification in both the model and the input.

**Padding:** One trivial way to control the model’s focus is to replace all input by the \(<\text{pad}>\) token, except the spans highlighted by the user. However, we find that this direct padding during evaluation results in drastically worse perplexity. To alleviate this problem, we randomly pad a portion of sentences in the input during the standard end-to-end finetuning, to make the model aware that only partial input would be provided.

**Keyword-control:** Keyword-based prompts (Fan et al., 2017; He et al., 2020) has been a popular approach for controllable text generation. We adapt this idea to our focus-control setting. During model finetuning, we prepend key-phrases extracted from the reference target sequence to the original input. We utilize Yake (Campos et al., 2020), which is an unsupervised keyword extraction method. During evaluation, we extract and prepend key-phrases extracted from the highlighted sentences.

**Attention-offset:** As a direct way to control the model’s attention, we add a positive scalar offset \(s^{\text{offset}}\) to the cross-attention heads before the softmax operation (Equation 1), for the highlighted...
Table 2: Main evaluation results on the PersonaChat and CNN/Dailymail datasets with annotated highlights. The proposed focus vector approach shows strong performance across different metrics.

| Model              | PersonaChat | CNN/Dailymail |
|--------------------|-------------|---------------|
|                    | PPL         | ROUGE-1/2/L   | BERTScore    | PPL         | ROUGE-1/2/L   | BERTScore    |
| vanilla (w.o. highlight) | 28.73       | 17.02/2.73/14.52 | 85.41       | 4.51        | 43.48/21.01/30.98 | 89.23       |
| padding            | 38.93       | 16.69/2.80/13.72 | 84.42       | 19.62       | 39.31/18.44/28.67 | 88.34       |
| keyword-control    | 23.64       | 17.31/3.02/14.81 | 85.58       | 4.56        | 43.81/21.08/31.15 | 89.26       |
| attention-offset   | 23.79       | 21.10/3.77/17.54 | 86.04       | 4.49        | 43.90/20.64/31.26 | 89.28       |
| focus-vector       | 22.51       | 20.81/3.98/17.58 | 86.13       | 4.48        | 45.92/23.03/32.98 | 89.78       |

Table 3 shows generation samples from different focus-control approaches for PersonaChat. Spans of the generation that are relevant to the highlighted persona are marked in red. Comparing to the generation from the vanilla model, the generations from both attention-offset and focus-vector are highly relevant to the respective highlighted persona. One generation from att-offset is a little erratic (“I am petro, my dog”), which may be due to the inflexibility of att-offset.

4.2 Results and Analysis

During evaluation, human-annotated highlights are fed to the model. In addition to perplexity, we evaluate the generations from different approaches using two popular NLG metrics: ROUGE (Lin, 2004), and BERTScore (Zhang et al., 2019).

We show the main results in Table 2. As expected, the padding baseline has poor performance, as a large portion of input is masked out. Comparing to various baselines, focus-vector obtains significantly improved ROUGE and BERTScore on both tasks. This validates the motivation of this work: focus-vec is effective in steering the model’s focus, which leads towards the desired generation. For CNN/Dailymail, the perplexity of focus-vector is close to the vanilla model even though there is a large difference in ROUGE. We believe this is due to the constrained nature of the summarization task and how perplexity is computed: once the model observes the first few tokens, it is easy to figure out what the current highlight is. The other two metrics, on the other hand, are based on the actual generation, and therefore does not have this issue.

The performance of keyword-control, although better than the vanilla model, is inferior to attention-offset and focus-vector. We surmise this is due to the following two weaknesses: First, key-phrases can not fully represent the highlighted span. Second, there is a discrepancy of where the key-phrases are extracted between training and evaluation.

Whether the attention distribution faithfully explains a model’s predictions is the subject of much debate (Jain and Wallace, 2019; Wiegreffe and Pinter, 2019; Bastings and Filippova, 2020). Therefore this direct modification of the attention head may not be the optimal solution for focus control. Our proposed focus-vector framework, on the other hand, utilizes attribution methods, and directly operates on the encoder embeddings.

\[
\alpha'_{i,j} = \text{softmax}_{i \in \{1, \ldots, n\}} \left( \frac{k(h_L^j) \cdot q_i}{\sqrt{d}} + s_{\text{offset}} \cdot \mathbb{I}_{[i-1]} \right),
\]

where \(s_{\text{offset}}\) is a hyper-parameter, and is applied to all cross-attention heads in the decoder. We tune \(s_{\text{offset}}\) on the human-annotated development set in a fine-grained manner. More details are given in Appendix C.

4.2 Results and Analysis

During evaluation, human-annotated highlights are fed to the model. In addition to perplexity, we evaluate the generations from different approaches using two popular NLG metrics: ROUGE (Lin, 2004), and BERTScore (Zhang et al., 2019).

We show the main results in Table 2. As expected, the padding baseline has poor performance, as a large portion of input is masked out. Comparing to various baselines, focus-vector obtains significantly improved ROUGE and BERTScore on both tasks. This validates the motivation of this work: focus-vec is effective in steering the model’s focus, which leads towards the desired generation. For CNN/Dailymail, the perplexity of focus-vector is close to the vanilla model even though there is a large difference in ROUGE. We believe this is due to the constrained nature of the summarization task and how perplexity is computed: once the model observes the first few tokens, it is easy to figure out what the current highlight is. The other two metrics, on the other hand, are based on the actual generation, and therefore does not have this issue.

The performance of keyword-control, although better than the vanilla model, is inferior to attention-offset and focus-vector. We surmise this is due to the following two weaknesses: First, key-phrases can not fully represent the highlighted span. Second, there is a discrepancy of where the key-phrases are extracted between training and evaluation.

The performance gap (in ROUGE/BERTScore) between focus-vector and attention-offset is larger on the CNN/Dailymail dataset. We believe this is because the BART model has a deeper encoder than the Blenderbot model. As the encoder grows deeper, the embeddings become more “contextualized” and its identifiability (Brunner et al., 2020) degrades. And since the decoder attends to the last layer of the encoder, this direct manipulation of attention weights could be ineffective with deep encoders.

Table 3 shows generation samples from different focus-control approaches for PersonaChat. Spans of the generation that are relevant to the highlighted persona are marked in red. Comparing to the generation from the vanilla model, the generations from both attention-offset and focus-vector are highly relevant to the respective highlighted persona. One generation from att-offset is a little erratic (“I am petro, my dog”), which may be due to the inflexibility of att-offset.

We defer the generation examples for CNN/Dailymail to Table 6 and Table 7 (Appendix D) due to space constraints. We observe that the generation from focus-vector is more focused on the highlighted inputs. On the other hand, attention-offset’s generation still remains similar to the vanilla model.

In Figure 3, we study how the outputs of attribution methods (attention-weight and grad-norm) change with different approaches (vanilla, focus-
Table 3: Generation samples from different attention control approaches for PersonaChat. The inputs on both sides are identical, except a different piece of persona is highlighted (marked in bold), which leads to different generations for approaches with control. Another example is provided in Table 5 (Appendix D).

vector and attention-offset) for the CNN/Dailymail example (Table 6). Note that in this analysis, for the attribution methods we set the target $y$ to be the decoded output from the respective modeling, instead of the reference summary. The highlighted sentences are marked by the red rectangles.

We observe that for both attention-weight and grad-norm, the application of focus vector makes the highlighted sentences obtain the highest attribution scores, and the scores differ significantly from the vanilla model. In some of the non-highlighted sentences (marked by the blue rectangles), attention-offset is not strong enough to significantly reduce its attribution. We also tried larger values of $s_{offset}$ for attention-offset but found it lead to performance degradation. This analysis shows that despite the small number of parameters associated with the focus vectors, they are able to effectively steer the model’s focus. We provide a simple visualization of the trained focus-vector parameters in Figure 3 (Appendix D).

Ablation Studies Table 4 shows several variants of focus vector on CNN/Dailymail. We first tune the hyper-parameters of focus vector only with the original dev set with $e_{str}$, instead of human-annotated highlights. Despite this discrepancy, focus vector still achieves strong performance on the test set. This result shows that the use of human-annotated dev set is not crucial for our framework. We then conduct an ablation study where we only apply focus vector on the first or last layer of the encoder, which reduces the number of parameters. We find that this results in marginal performance degradation. Finally, we jointly finetune focus vector and the whole model with the same loss function (Equation 7), where a separate and smaller learning rate is used for the model. Interestingly, the gain from model finetuning is very limited, which demonstrates the effectiveness of focus vector.

Table 4: Performance of different variants of focus-vector trained on CNN/Dailymail. all-layer* refers to our proposed modelling (also reported in Table 2).

| Model                  | CNN/Dailymail | BERTScore |
|------------------------|---------------|-----------|
|                       | PPL           | ROUGE-1/2/L |           |
| all-layer*             | 4.48          | 45.92/23.03/32.98 | 89.78  |
| ori-dev with $e_{str}$ | 4.50          | 46.41/22.69/32.48 | 89.62  |
| only first layer       | 4.48          | 45.67/22.63/32.45 | 89.59  |
| only last layer        | 4.48          | 46.06/22.84/32.69 | 89.69  |
| plus model finetune    | 4.49          | 46.65/23.54/33.30 | 89.82  |

Table 5: Performance of different attention control approaches for PersonaChat. The inputs on both sides are identical, except a different piece of persona is highlighted (marked in bold), which leads to different generations for approaches with control. Another example is provided in Table 5 (Appendix D).

5 Related Work

Our proposed focus-vector framework is closely related to the research topics of controllable text generation, LM adaptation, and attention/attribution analysis, which we review below.

Controllable Text Generation Prior work on controllable summarization introduced various types of control mechanisms. Fan et al. (2017); Saito et al. (2020) extract entity, keyword or length, as additional supervision during training. Gehrmann et al. (2018) trains a token-level content selection module, where the supervision is by aligning the summaries to the documents. (Song et al., 2021) proposes a two-staged generation strategy and Goyal et al. (2021) incorporates multiple decoders into a transformer framework. Some recent work (He et al., 2020; Dou et al., 2020) uses prompts to control the generation. Lexically constrained decoding (Post and Vilar, 2018) has also
been used to enforce certain key phrases to be included in the summary (Mao et al., 2020).

Existing work on controllable dialogue response generation include using conditional variational autoencoders (Zhao et al., 2017; Li et al., 2020a), and incorporating external knowledge into the conversational agent using knowledge graphs (Cui et al., 2021; Moon et al., 2019), unstructured documents (Kim et al., 2020), or dialogue context (Zhao et al., 2020). There is also a line of work on promoting the diversity or consistency of the model (Li et al., 2016a; He and Glass, 2019; Li et al., 2020b).

In open-ended language generation, a series of approaches have been proposed to control for some attribute (e.g., topic) of the generation (Keskar et al., 2019; Dathathri et al., 2020; Krause et al., 2020; Yang and Klein, 2021). Some of these studies utilize a trained classifier to guide the generative model towards the desired attribute.

**LM Adaptation** Our proposed focus vector framework is also inspired by a series of recent works on prompting or light-weight LM adaptation. Li and Liang (2021), followed by Lester et al. (2021) and Zhong et al. (2021), propose prefix tuning, where continuous task-specific input vectors are tuned to adapt the pretrained LM to a downstream task with supervised data, and the model is kept fixed.

There is also a line of works on adapter-tuning, which insert and finetune task-specific layers (adapters) between each layer of the pretrained LM (Houlsby et al., 2019; Lin et al., 2020; Pfeiffer et al., 2021). More recently, Guo et al. (2021) and Ben-Zaken et al. (2020) propose to finetune only a small subset of a pretrained model’s parameters, and achieves strong performance on GLUE or other tasks (Wang et al., 2018; He et al., 2021).

**Attention Analysis and Attribution Methods** Due to the ubiquity of the attention module in current NLP models, various work has studied how the module captures linguistic phenomena in the input (Clark et al., 2019; Kovaleva et al., 2019; Kobayashi et al., 2020). It has also been used as a tool to interpret the model’s predictions (Wang et al., 2016; Lee et al., 2017; Ghaeini et al., 2018).

Recently, there have been a series of studies discussing the use of attention weights for interpretability (Jain and Wallace, 2019; Wiegreffe and Pinter, 2019; Bastings and Filippova, 2020; Serre and Smith, 2019), and it has been argued that attribution methods are a better choice to explain the model’s predictions. The poor alignment performance of attention weights that we get in Table 1, on some level, are in agreement with that argument. Our work is also related to the line of work on interpreting black box models through rationales (Lei et al., 2016; Bastings et al., 2019), which are typically (discrete) subsets of the input that are used to predict the output. Finally, several recent works (Xu and Durrett, 2021; Ding and Koehn, 2021) have compared different attribution methods for interpreting NLP models.

In comparison to the aforementioned works, our major innovations are two fold: (1) Our goal is to control the focus of pretrained models, and thereby steer the model’s generation, and our proposed focus vectors are compatible with the standard transformer architecture; (2) We utilize attribution methods to obtain automatic annotations for focus-vector training. Therefore, our framework can be applied to a wide range of NLG applications.

**6 Conclusion**

In this work we propose the focus vector framework as a light-weight solution to control the focus of pretrained transformer models. It has two major advantages: (1) Focus vectors act as simple transformations to the embeddings in the encoder, and the transformer model is kept fixed; (2) Attribution methods are utilized to get automatic highlight labels for training focus vectors.

We test our approach on two tasks: dialogue response generation, and abstractive summariza-
tion. For evaluation, we collect data where the highlight-generation pairs are annotated by humans. Experiments show that the trained focus vectors are effective in steering the model to generate output text that is relevant to the specified highlights.

Appendices

A End-to-end Datasets

The PersonaChat dataset contains 8,939 dialogues for training, 1,000 for validation, and 968 for test. For each turn in the dialogue, we concatenate the persona of the speaker and the dialogue history as input, and train the base model to generate the current utterance. In some cases, the dialogue history is long and exceeds the input limit of the model, in which case we truncate the dialogue at the sentence level. The average number of sentences is around 11 after truncation.

The CNN/Dailymail dataset contains 287,113 training examples, and 13,368 / 11,490 examples for validation / test. We apply the same truncation strategy as PersonaChat during preprocessing. The processed articles have an average length of 748 tokens, and the reference summaries have an average length of 67 tokens.

B Human-annotated Evaluation Data Collection

To improve the quality of collected dataset, we design a qualification test, which the turkers need to pass before they can work on real assignments. The test is designed to help turkers understand our task better. For PersonaChat, we give turkers two dialogue samples with pre-selected highlights, and ask them to choose the appropriate response that not only continues the dialogue, but also is relevant to the highlights. For CNN/Dailymail, the turkers are shown two example articles and the corresponding reference summaries. We have already picked some highlights in the article, but there is one highlight missing. And the turker is required to pick the missing highlight. The interface for the PersonaChat qualification test is shown in Figure 5.

We also add multiple checks in our script to prevent trivial answers. We ban trivial copy&pasting from the given context. A time check is added that requires turker to spend at least 60 seconds on a single HIT. For the two assignments in PersonaChat, we add a content check that prevents duplicate highlights or response. We show our interface for PersonaChat in Figure 6. Despite these checks and the qualification tests, there still exist a small number of misbehaving turkers who attempt to cheat. Therefore we also manually monitor the incoming submissions, and ban misbehaving turkers and filter out their submissions.

More examples of our interface and instructions can be found in our uploaded data samples.

C Implementation Details

For the attention-offset baseline, we tune the offset \( s_{\text{offset}} \) in a fine-grained manner, on the human-annotated dev set. We first set a relatively large max value (100) and get 20 evenly spaced numbers inside the interval \((0, 100)\). Then we calculate model PPL on the dev set with \( s_{\text{offset}} \) set to these different offsets. Then we do another search in the interval that has lowest PPL. We repeat this iteration multiple times, and stops when PPL change is smaller than \( 1 \times 10^{-3} \). The final tuned value for Blenderbot is around 3.02, and around 0.17 for BART.

D Auxiliary Results and Examples

In Figure 4, we provide a simple visualization of the trained focus vectors of BART. To make the
figure easy to grasp, we randomly sample 50 dimensions (out of 768) of trained focus-vector parameters. In the figure only the trained parameters for the first encoder layer is shown, and we find that the patterns for the other layers are similar.

We first find that the learned scaling parameters are close to 1 and the bias parameters are close to zero. This implies that the transformation defined by the focus-vec is not drastic, and a relatively small tweak could be enough to steer the model’s focus.

An interesting pattern can be observed for the scaling vectors. $\theta_{\text{scale-nonfocus}}$ tends to down-scale the embedding, comparing to $\theta_{\text{scale-focus}}$. This matches our intuition that the embeddings on the non-highlighted positions should be down-played.
My parents did not want me. It's a dead end job so I am looking for something different. I was raised by my uncle and aunt.
