RESEARCH ARTICLE

The kinetics of the oxidation of ammonia on a V_{2}O_{5}/TiO_{2} SCR catalyst deactivated in an engine rig. Part I. Determination of kinetic parameters by simulation

Ingemar Odenbrand

1Department of Chemical Engineering, Lund University, P.O. Box 124, SE-221 00 Lund, SWEDEN

ABSTRACT

It is shown how the deactivation of a diesel SCR (Selective Catalytic Reduction) catalyst by compounds in the exhaust gases influences the kinetics of the catalyst. Results are given for the fresh (4.56 % V_{2}O_{5}/TiO_{2}) catalyst and the ones used in the rig for 890 h and 2299 h. The reactions of 700 ppm NH_{3} and 2 % O_{2} in Helium yielded N_{2}, N_{2}O, and NO at increasing temperatures. Simulations were performed with COMSOL Multiphysics using a 3-D model of the catalyst system. The experimental values of the products N_{2}, N_{2}O, and NO were very nicely fitted by the kinetic model used. All three ammonia oxidation reaction rates were of the first order in the concentration of NH_{3}.

Keywords: Oxidation of ammonia, poisoning and kinetics, Vanadia SCR diesel catalysts

1. INTRODUCTION

The Selective Catalytic Reduction (SCR) technique is today a compulsory method for mobile applications like marine and automotive diesel engines in many countries. Marine engines run under conditions, which resemble the ones in stationary diesel power plants. In 2017, there were hundreds of SCR units installed on diesel engines on ships [1]. The lubricating oil for the diesel engine is often a sour diesel engine is often a sour like marine and automotive diesel engines today a compulsory method for mobile applications. Koebel and Elsener [4] studied the removal of 1000 ppm NO with NH_{3} using commercial V_{2}O_{5}-WO_{3}-TiO_{2} catalysts. They do not state what ammonia reaction(s) they consider but state that the rates of ammonia oxidation reactions are about 500 times smaller than the SCR reaction ones. In 1993 Ozkan et al. [5] studied the role of ammonia oxidation in the SCR over vanadia catalysts. They found that N_{2}, N_{2}O, and NO were the products. In their extensive study [6] using nitrogen labelling, they found that the ammonia species giving N_{2} and N_{2}O have relative long residence times on the surface. The NO producing species are short-lived. Thus, three ammonia oxidation reactions are assumed. Duffy et al. [7], using V_{2}O_{5}/TiO_{2} catalysts with varying vanadia contents, also used isotopic labelling studies to conclude that below 300 °C the major product is H_{2}O. At higher temperatures, the product distribution is susceptible to the vanadia content of the catalyst. At 500 °C, 70 % of the product is H_{2}O. Pure V_{2}O_{5} produces significantly more N_{2}O, and at lower temperatures than a 1.4 wt % V_{2}O_{5}/TiO_{2} catalyst. As part of an SCR study, the kinetics of the partial ammonia oxidation giving N_{2} was studied between 250 and 300 °C by Elstathiou et al. [8]. They oxidised 1000 ppm NH_{3} by 2 % O_{2} with helium as background gas over an 8 mol % V_{2}O_{5}/TiO_{2} catalyst. The selectivity to
N\(_2\) was from 98.2 to 97.6 % decreasing with temperature. The rate of the ammonia oxidation was only from 1.8 to 2.4 % of the rate of the SCR reaction, much higher than stated above by Koebel and Elsener [4]. They [8] also studied the formation of N\(_2\)O between 320 and 380 °C. In this temperature range, the formation of N\(_2\)O is almost completely caused by the reaction of NH\(_3\) with NO. Djerad et al. [9] included all three NH\(_3\) oxidation reactions in their study on the effect of oxygen on the reaction rates. Using a 3%V, 9%W on titania catalysts, the effect of oxygen was small between 2 and 15 % O\(_2\). A maximum in the formation of N\(_2\) was observed at 425 °C. N\(_2\)O was formed above 300 °C while NO only above 425 °C. They found that the formation of N\(_2\)O from ammonia oxidation is important in the SCR process. So, we will include all three reactions in our simulation of the ammonia oxidation.

The inspiration for the present study comes from the excellent results obtained earlier using COMSOL Multiphysics as means of performing FEM analysis of catalytic reactors [10,11]. An excellent paper on global kinetic modelling of SCR over vanadia on titania was published by Roduit et al. [12]. Only the SCR reaction and the oxidation of NH\(_3\) to N\(_2\) were included though. They presented results on the ammonia coverage of the catalyst as a function of temperature and ammonia concentration. These values were the base for our assumed influence of temperature on the coverage of NH\(_3\). Their values of the adsorption energy of NH\(_3\) was not used. Instead, we relied on the value -100 to -130 kJ mol\(^{-1}\), as presented by Koebel and Elsener [4].

There are not too many studies published using COMSOL Multiphysics to simulate catalytic reactors. One of them is performed by Chen et al. [13]. They used their study to optimise the performance of the reactor for the SCR using the NH\(_3\) to N\(_2\) oxidation reaction and the SCR reaction.

We could not find very much if any, kind of information in the literature on the effect of deactivation on the kinetics of ammonia oxidation over vanadia catalysts. We presented before [3] how the poisons accumulate along the catalyst monolith. The present study presents a simulation of the kinetics of the oxidation of NH\(_3\) with O\(_2\) and how it depends on the degree of the poisoning of the catalyst. The catalysts in this study consist of a thin layer of active components supported on cordierite. Therefore, the effect of deactivation will be more easily detected in our experiments than in experiments on full catalysts.

The data used in the study were measured at two increasing degrees of poisoning by the compounds most likely to be present in commercial use. Therefore, the result could be used in the design of new catalysts for diesel engines which are deactivated by compounds in the lubrication oil.

2. MATERIALS AND METHODS

2.1. Preparation and deactivation of the catalyst samples

The catalysts used were made in house by a Swedish catalyst manufacturer and consisted of 5.64 % V\(_2\)O\(_5\) on TiO\(_2\) (Rhone Poulenc DT[8]) on the support of cordierite from Corning with a CPSI of 400. Details on the preparation, deactivation and characterisation can be found in Odenbrand [3]. The deactivation was performed in an engine rig using Swedish class 1 diesel fuel. The deactivation cycle, 1 hour long, had a mean temperature of 470 °C and a maximum temperature of 570 °C for 7.5 min in each cycle. Samples were taken from the fresh catalyst, and the catalysts used for 890 and 2299 h in the rig. The accelerated test was supposed to simulate the regular running of a truck for up to 500 000 km (given by the catalyst manufacturer).

2.2. Measurement of catalyst activity and selectivity

The centre part (9 x 9 channels wide) of the 10 cm long and 2.5 cm wide monolithic catalysts were cut into 1 cm mini monoliths along their axis. Only piece five from the inlet was used in the ammonia oxidation experiments. The activity and selectivity in the oxidation of ammonia with O\(_2\) were measured at about 700 ppm NH\(_3\) and 2 % O\(_2\). The pressure was 1.24 bar (Space velocity 45 000 h\(^{-1}\)). Temperatures were from 340 to 460 °C at 20 °C intervals. Helium was used as a background gas containing about 3000 ppm of Ar for internal calibration as described before [11]. A Balzer QMG 311 mass spectrometer was used for gas analysis. A chopping device was used to decrease the influence of the background signal. The spectra were recorded using peaks 17, 18, 28, 30, 44 and 46 for NH\(_3\), H\(_2\)O, N\(_2\), NO, O\(_2\), Ar, N\(_2\)O and NO\(_2\). The spectrum was scanned twice first with an open and then with a closed chopper. By subtraction, a difference spectrum representing the composition in the gas stream was obtained. Experimentally determined splitting factors and sensitivity factors, determined from gases of known compositions, were used to calculate the concentrations with a computer program. The background concentrations of N\(_2\) and H\(_2\)O were 37.7 ± 0.2 and 31.4 ± 2.5 ppm respectively showing the accuracy of the mass spectrometric data. Inlet concentrations of NH\(_3\) varied somewhat between the three experiments and were 725 ± 18 ppm. The actual concentrations were used in the simulation of each series of experiments.

2.3. Modelling of the catalyst reactions

The kinetic scheme used in the simulations is based on first-order reactions in the concentration of ammonia for reactions 2, 4 and 5 in Table 1. In all cases, the effect of oxygen, present in excess (2 %), is included in the rate constant. The eventual effects of any diffusion limitations are also included.

The reactions are demanding more and more oxygen and are being more important at increased temperatures, the higher the number of the reaction is. It is only reactions 2, 4 and 5 that have a significant influence on the kinetics of ammonia oxidation because of deficient concentrations of NO in the system. Thus, reactions 1 and 3 are omitted in this study. Table 2 shows the physiochemical data used in the simulation in non-isothermal and in isothermal cases.
in 2 µolid density of the active catalyst layer is calculated. For calculation of the apparent density, the density of V2O5 is 3825 kg m⁻³ and for TiO2 3780 kg m⁻³. The densities for V2O5 and TiO2 were used in calculating the solid density of the active layer containing 18.2% V2O5. The apparent density, together with the amount of the active phase (18.2 wt %), is used in calculating the thickness of the active layer, which is 21 mm, and was used in the simulations. The catalyst layer was supposed to cover all inside walls of the monolith. For calculation speed reasons only one-eighth of the whole reactor was simulated. The mesh used is shown in Fig 1.

The heat source was from the chemical reactions. The reactor, made of quartz glass, is 100 mm long with the bottom of the catalyst monolith (1 cm long) positioned 60 mm from the inlet on a plug of glass wool. The monolith was surrounded by quartz wool to stop gas bypassing the catalyst. Only a small part of the simulated system is shown in Fig 2 in order to show the mesh used in the calculations. The monolith contains 81 channels, but the model simulates only one of them.

**Table 1. Chemical reactions and kinetic expressions used in the simulations**

| Reaction number | Global reaction | Rate expression |
|-----------------|-----------------|-----------------|
| 1               | 4NH₃+4NO+0.02→4N₂+6H₂O | \( r_1 = A \times \exp\left(-\frac{E_1}{RT}\right) \times c_{NH3}^3 \) |
| 2               | 4NH₃+3O₂→2N₂+6H₂O | \( r_2 = A \times \exp\left(-\frac{E_2}{RT}\right) \times c_{NH3}^4 \) |
| 3               | 4NH₃+4NO+0.02→4N₂+6H₂O | \( r_3 = A \times \exp\left(-\frac{E_3}{RT}\right) \times c_{NH3}^2 \) |
| 4               | 4NH₃+5O₂→4N₂+6H₂O | \( r_4 = A \times \exp\left(-\frac{E_4}{RT}\right) \times c_{NH3}^3 \) |
| 5               | 4NH₃+5O₂→4N₂+6H₂O | \( r_5 = A \times \exp\left(-\frac{E_5}{RT}\right) \times c_{NH3}^2 \) |

\[ \theta_{NH3} = K_{NH3} c_{NH3}/(1+K_{NH3} c_{NH3}) \]

\[ K_{NH3} = A \times \exp(-E_0/(RT)) \]

**Table 2. Physical data used in the Transport of Diluted Species and Free and Porous Media Flow nodes in the COMSOL program**

| Parameter | Open channel | Catalyst Layer | Cordierite¹ |
|-----------|--------------|----------------|-------------|
| Diffusion coefficients in the fluid *10⁵ (m² s⁻¹) | 9.83 - 13.22 | n.a. | n.a. |
| Diffusion coefficients in catalyst (m² s⁻¹) | n.a. | Deff=ε/c*Diffuid | n.a. |
| Porosity of catalyst (ε) | n.a. | 0.4 | n.a. |
| Density (kg m⁻³) | 0.635 – 0.760 | 2295 | 2300 |
| Dynamic viscosity *10⁵ (Pas) | 9.25 – 10.39 | n.a. | n.a. |
| Permeability (m²) | n.a. | 6*10⁻⁸ [11] | n.a. |

| Heat capacity (J (kg⁻¹ K⁻¹)) | 649 | 1050 | 880 |
| The ratio of specific heats | 1 | 1 | 1 |

n.a. Not applicable

¹ Cordierite was substituted by concrete, and alumina was used instead of titania for physical data.

The reactor, made of quartz glass, is 100 mm long with the bottom of the catalyst monolith (1 cm long) positioned 60 mm from the inlet on a plug of glass wool. The monolith was surrounded by quartz wool to stop gas bypassing the catalyst. Only a small part of the simulated system is shown in Fig 2 in order to show the mesh used in the calculations. The monolith contains 81 channels, but the model simulates only one of them.
Concentrations measured at the end of the reactor were shown by the simulations to be even over the channel cross-section. The measured concentrations are plotted versus the temperature at the exit of the monolith. Manual changes in kinetic parameters are performed in order to fit the simulated values to the experimental ones according to the method described before [11, 12]. First, the concentration of N₂ was fitted with parameters in reaction 2. Then the concentrations of N₂O and NO were fitted according to reactions 4 and 5. Both these components were of the same magnitude, so they were fitted simultaneously.

3. RESULTS AND DISCUSSION

3.1. Apparent kinetic data

Table 4 shows apparent kinetic data which were obtained from assumed first-order dependence on the concentration of NH₃ and experimental conversions and selectivities. These parameters were used as starting values in the simulations.

Rates are given at 340 and 460 °C except for rNO for the fresh catalyst and the one used for 890 h where the lowest temperature is 380 °C.

The activation energies are decreasing with an increased degree of poisoning, as observed before [15, 16]. The poisoning has the most significant effect on the formation of NO. The results of this study can be compared to the results of Chen and Tan [13] who also used COMSOL Multiphysics in the simulation of, in their case, a catalyst bed. Their value of E₂ is 84.4 kJ mol⁻¹ when corrected for diffusion limitations while our apparent value is 74.4 kJ mol⁻¹ for the fresh catalyst. The values of k₂ were 6.73*10⁷ and 4.13*10⁸ s⁻¹, respectively. Good consistency is obtained.
Table 4. Apparent kinetic parameters in the oxidation of 700 ppm NH$_3$ with 2% O$_2$ in Helium at 1.24 atm from 340 to 460 °C on all three catalysts

| Parameter | Fresh     | 890 h     | 2299 h    |
|-----------|-----------|-----------|-----------|
| $A_2$ (m$^3$ g$^{-1}$ s$^{-1}$) | 9.79*10$^5$ | 9.79*10$^5$ | 8.95*10$^4$ |
| $E_2$ (kJ mol$^{-1}$) | 74 | 78 | 52 |
| $r_{x2}$ (mol g$^{-1}$ s$^{-1}$) | 4.27*10$^{-8}$4.27*10$^{-7}$ | 4.27*10$^{-8}$4.12*10$^{-7}$ | 4.71*10$^{-8}$2.62*10$^{-7}$ |
| $A_3$ (m$^3$ g$^{-1}$ s$^{-1}$) | 4.51*10$^6$ | 6.68*10$^5$ | 5.53*10$^5$ |
| $E_3$ (kJ mol$^{-1}$) | 123 | 137 | 123 |
| $r_{x30}$ (mol g$^{-1}$ s$^{-1}$) | 2.51*10$^{-9}$1.07*10$^{-7}$ | 2.99*10$^{-8}$1.88*10$^{-7}$ | 1.88*10$^{-8}$1.31*10$^{-7}$ |
| $A_5$ (m$^3$ g$^{-1}$ s$^{-1}$) | 3.94*10$^{13}$ | 5.69*10$^{10}$ | 4.50*10$^{10}$ |
| $E_5$ (kJ mol$^{-1}$) | 201 | 161 | 141 |
| $r_{x50}$ (mol g$^{-1}$ s$^{-1}$) | 3.54*10$^{-10}$1.62*10$^{-8}$ | 1.32*10$^{-9}$2.34*10$^{-8}$ | 7.53*10$^{-10}$5.30*10$^{-8}$ |

3.2. Results from non-isothermal simulations

Fig 3 shows the temperature rise obtained in a non-isothermal simulation. The temperature increase was shown to be only 0.145 °C at 460 °C in the oxidation of 729 ppm NH$_3$ for the fresh catalyst. The temperature increase is about the same for all three catalysts. These values are small enough so that the assumption of an isothermal system could be used. Even so, the system was simulated as a non-isothermal one first to study some of its properties. One of the most crucial property is the temperature which influences the rate of reactions in an exponential manner.

The catalyst monolith starts at 0 and ends at 0.01 m in Fig 3. Increased temperatures are seen both before and after the monolith part of the system caused by heat conduction — the temperature increases along the system axis in a manner typical for exothermal reactions. A maximal temperature is reached at 0.003 m from the inlet of the monolith.

Fig 4 shows how the velocity in the reactor is increased from about 0.39 m s$^{-1}$ in the centre before the monolith to about 0.55 m s$^{-1}$ inside it. The smaller open channel inside the monolith than in the empty reactor causes this. The flow is developing to a laminar one at about 1 mm from the inlet (not shown here). The pressure drops over the monolith by 5.1*10$^{-5}$ bar and by 3.15*10$^{-4}$ bar over the whole reactor. The total pressure drop over the monolith was only 0.4% of the actual pressure in the system.

Fig 5 shows how the NH$_3$ is evenly distributed over the cross-section of the channel, the catalyst layer and the cordierite wall. The lowest value is 545.9 ppm in the centre of the channel, increasing to 550.3 ppm in the upper part of the catalyst layer. That is the concentration is constant within 0.8% at these conditions. The heat of the reaction is very well distributed over the exit of the monolith, where the maximum temperature difference is only 0.15 K (not shown here). Fig 6 shows the amount of NH$_3$ "converted" as a function of the position in the monolith and measured in the centre of the channel.

Fig 3. The temperature along the axis of the channel around the monolith for the catalyst used for 890 h. Oxidation of 729 ppm NH$_3$ with 2% O$_2$ in Helium. The inlet temperature was 733 K (460 °C).
Fig 4. Velocity in the centre of the channel in the reactor. The inlet temperature was 733 K (460 °C), p 1.236 bar

Fig 5. The concentration of NH\textsubscript{3} (ppm) across the surface of the channel, the fresh catalyst layer and the monolith wall at the exit of the monolith. The inlet temperature was 733 K (460 °C)

Fig 6. The conversion of NH\textsubscript{3} along the axis of the channel for the fresh monolith. The inlet temperature was 733 K (460 °C)
In the inlet part of the monolith, there is a definite "conversion" caused by a change in concentration as an effect of the increased temperature in this position (Fig 3). One would not expect a conversion before the gas stream is in contact with the catalyst. That is why we use apostrophes around conversion.

The rate of formation of nitrogen is 60 times higher than the rate of formation of nitrous oxide at 340 °C (613 K in Fig 7). At 460 °C the ratio is only 2.26. The rate of formation of NO is even lower and is only 0.39 % of the rate of formation of nitrogen at 340 °C. At 460 °C it increases to 8.6 % of the rate of formation of nitrogen.

Fig 7. The rates of the individual reactions as a function of the temperature for the fresh catalyst

3.3. Results from isothermal simulations

Since the maximal temperature increase is so low, the rest of the simulations were performed as an isothermal case. Fig 8 shows the concentrations of products formed in the oxidation of about 800 ppm NH3 with 2 % O2 along with the simulated values for the fresh catalyst, for the catalyst used for 890 h in the rig, and for the catalyst used for 2299 h.

For the fresh catalyst, the fit to N2 is not very good at low and high temperatures. The experimental values show a curved upward deviation from the simulated ones for the fresh catalyst and the one used for 890 h. The best fit for N2 is obtained on the catalysts used for 2299 h. The SCR is also active at high temperatures where we know that small amounts of NO are formed from NH3. So, the high experimental values at temperatures above 700 K values can be explained if the SCR reaction takes place to a small extent. Figure 8 shows that it is quite easy to get a good fit for the contents of N2, N2O, and NO except for the lowest temperatures.

The simulated concentration of H2O is shown in Fig 8 and are also much higher than the experimental ones but with an increased discrepancy at increased temperatures. Also, the experimental value of H2O is lower for the catalyst used for 2299 h than for the other ones. Whether this is significant is hard to say.

The simulated concentration of H2O is shown in Fig 8 and are also much higher than the experimental ones but with an increased discrepancy at increased temperatures. Also, the experimental value of H2O is lower for the catalyst used for 2299 h than for the other ones. Whether this is significant is hard to say.

Fig 9 shows the simulated and experimental values of NH3 when the fitting is performed on the formation of N2. The best fit is obtained at an intermediate temperature.

At 733 K, the experimental value is 300 ppm, while the simulated one is 400 ppm. All components are measured precisely as before [11], so some effects of the deactivation could explain the not too good fit for H2O (Fig 8) and NH3 (Fig 9). A plausible one is that Ca phosphates are present on the deactivated catalysts reacting with and consuming the gas-phase water [17]. This reaction will not give a long-lasting effect, in any case. Furthermore, it will not explain that similar behaviour is observed for the fresh catalyst. A fact is that the mass balance in these experiments is not as correct as in earlier work [11]. The discrepancy increases at increased temperatures. For Nout/Nin the mean is 0.962±0.034, and for Hout/Hin it is 0.847±0.074. Values at the lowest temperature are close to 1. For the earlier study, the standard deviation was only 0.9 % and independent on temperature. Thus, the use of N2 instead of NH3 for the fitting procedure.

Table 5 shows the obtained kinetic parameters after fitting the simulated concentrations of N2, N2O, and NO to the experimental ones at increasing temperatures for the three catalysts studied.
Fig 8. Simulation of the oxidation of about 700 ppm NH$_3$ with 2 % O$_2$ at 1.24 bar over the fresh catalyst and the ones used for 890 and 2299 h. Experimental values for N$_2$ (stars), H$_2$O (asterisks), N$_2$O (diamonds), and NO (circles). Lines are simulated values.
At 340 °C the rates of 2 = 3 decrease on further use [11]. A decrease and NO all decrease when the catalyst is poisoned. The activation energies for the formation of N\textsubscript{2}O (r\textsubscript{2}) increase by 41 % after 890 h and decreases by 2 % after 2299 h compared to the fresh catalyst. Earlier results, where an increased content of sulphur increases the rate of reaction in the SCR, especially at low temperatures [15,16] agrees with this finding. At 340 °C the rates of formation of N\textsubscript{2}O (r\textsubscript{2}) increase by 41 % after 890 h and increase by 273 % after 2299 h from the value for the fresh catalyst. At 460 °C the rate increase after 890 h by 73 % and by 40 % after 2299 h. The lowest rate of formation of NO at 340 °C is observed on the fresh catalyst increasing by 242 % after 890 h and decreases by 29 % after 2299 h. At higher temperatures, the effects are smaller but except for the catalyst used for 2299 h where an increase by 382 % is observed.

The activation energies for the formation of N\textsubscript{2}, N\textsubscript{2}O, and NO all decrease when the catalyst is poisoned. The same effect has been observed before [11]. A decrease in the pre-exponential factor, proportional to the number of active sites, is also observed.

Efstathiou and Fliatoura [8] determined the apparent activation energy of 61.4 kJ mol\textsuperscript{-1} for the oxidation of 1000 ppm NH\textsubscript{3} with 2 % O\textsubscript{2} in Helium for an 8 % V\textsubscript{2}O\textsubscript{5}/TiO\textsubscript{2} catalyst from experimental rates. The rate of N\textsubscript{2} formation at 300 °C was 17.2*10\textsuperscript{-6} mol g\textsuperscript{-1} min\textsuperscript{-1} compared to the value in this study of 9.3*10\textsuperscript{-2} mol m\textsuperscript{-3} s\textsuperscript{-1} (2.4*10\textsuperscript{-6} mol g\textsuperscript{-1} min\textsuperscript{-1}) at 340 °C. Their E\textsubscript{2} was 61.4 kJ mol\textsuperscript{-1} compared to the value in this study of 64 kJ mol\textsuperscript{-1}. The experimental rate data of Efstathiou and Fliatoura [8] were obtained on the powdered catalyst, but the particle size is not mentioned, so an estimation of diffusion influence is not possible. Taking into consideration that the data from this study are obtained on a layered monolithic catalyst, the activities are similar.

Table 5. Simulated kinetic parameters in the oxidation of 700 ppm NH\textsubscript{3} with 2 % O\textsubscript{2} in Helium at 1.236 bar from 340 to 460 °C as a function of time of use for the three catalysts studied. Rates are given at inlet conditions.

| Parameter | Fresh | 890 h | 2299 h |
|-----------|-------|-------|--------|
| A\textsubscript{2} (s\textsuperscript{-1}) | 1.51*10\textsuperscript{6} | 3.93*10\textsuperscript{5} | 1.62*10\textsuperscript{5} |
| E\textsubscript{2} (kJ mol\textsuperscript{-1}) | 64 | 56 | 52 |
| r\textsubscript{2} (mol m\textsuperscript{-3} s\textsuperscript{-1}) | 9.3*10\textsuperscript{-2} - 5.9*10\textsuperscript{-1} | 1.3*10\textsuperscript{-1} - 5.8*10\textsuperscript{-1} | 1.0*10\textsuperscript{-1} - 4.2*10\textsuperscript{-1} |
| A\textsubscript{4} (s\textsuperscript{-1}) | 7.17*10\textsuperscript{10} | 5.78*10\textsuperscript{10} | 4.01*10\textsuperscript{9} |
| E\textsubscript{4} (kJ mol\textsuperscript{-1}) | 138 | 133 | 118 |
| r\textsubscript{4} (mol m\textsuperscript{-3} s\textsuperscript{-1}) | 2.2*10\textsuperscript{-3} - 1.5*10\textsuperscript{-3} | 3.1*10\textsuperscript{-3} - 2.6*10\textsuperscript{-3} | 6.0*10\textsuperscript{-3} - 2.1*10\textsuperscript{-3} |
| A\textsubscript{5} (s\textsuperscript{-1}) | 1.25*10\textsuperscript{11} | 9.12*10\textsuperscript{10} | 4.36*10\textsuperscript{9} |
| E\textsubscript{5} (kJ mol\textsuperscript{-1}) | 153 | 146 | 124 |
| r\textsubscript{s} (mol m\textsuperscript{-3} s\textsuperscript{-1}) | 2.4*10\textsuperscript{-4} - 2.2*10\textsuperscript{-2} | 5.8*10\textsuperscript{-4} - 4.2*10\textsuperscript{-2} | 2.0*10\textsuperscript{-3} - 8.4*10\textsuperscript{-2} |

The formation rates of N\textsubscript{2} obtained in the simulations, as shown in Table 5, increase at 340 °C for the catalyst used for 890 h compared to the fresh catalyst but decrease on further use. At 460 °C it decreases by 2 % after 890 h and decreases by 29 % after 2299 h compared to the fresh catalyst. Squares are experimental values while the line is the simulated ones.
structure with a catalyst layer. Their values of the pre-exponential factor and the activation energy for the formation of \( \text{N}_2 \) were 6.8*10^10 and 85 compared to the values of this study of 1.51*10^14 and 64 kJ mol^{-1}, respectively. Salehi et al. [18] also used first order in ammonia concentration for the rate of formation of \( \text{N}_2 \).

A calculation of the rate \( r_2 \) at 340 °C from their data gives 0.256 mol m^{-3} s^{-1} compared to the value from this study of 9.3 *10^{-2} mol m^{-3} s^{-1} (Table 5). They are in the same magnitude.

Om et al. [19] studied, using Fluent, the SCR in a monolith isothermally. The concentrations of NO and \( \text{NH}_3 \) were in the range of 1000 ppm, so we believe that their simulation should have been non-isothermal for more precise results. Schaub’s data [20] were taken from an experimental study on a catalytic filter consisting of very small catalyst particles, so the values should be close to intrinsic values. Their values of \( k_2 \) and \( E_2 \) were 6.73*10^9 and 85.4 kJ mol^{-1} while the values of this study were 1.51*10^14 and 64 kJ mol^{-1}, respectively (Table 5). Calculation of nitrogen formation rates at 340 °C from the data of Om et al. [19] gave a value of 0.049 while the value in this study was 0.093 mol m^{-3} s^{-1}. The rates are in the same range at this temperature. At 460 °C, their rate was 4.8, and the value of this study was 0.59 mol m^{-3} s^{-1}.

Chen and Tan [13] simulated a catalytic particle bed for the SCR process. In their simulation, the rate constant for the formation of \( \text{N}_2 \) from \( \text{NH}_3 \) by oxidation (\( k_2 \)) was 6.73*10^{10}exp(-84400/R/T). This study’s result was a rate constant expression of 1.51*10^{14} exp(-64000/R/T). Thus, at 460 °C the rate constants are 65 and 42 s^{-1} respectively, which is again in the same range.

Millo et al. [22] simulated the SCR on a filter catalyst for automotive applications. Besides the standard SCR, the fast and slow SCRs, the oxidation of \( \text{NH}_3 \) to \( \text{N}_2 \) was used as model reactions. The activation energy (\( E_2 \)) was 144.6 kJ mol^{-1} much higher than this study’s value of 57 kJ mol^{-1}. Their rate expression was \( r_2 = k_2 \* \text{NO} \* \text{CO}_2 \) and includes the dependence on the oxygen concentration making direct comparisons unsuitable. Their experiments also included water which would decrease the rate of all reactions.

4. CONCLUSIONS

In this study the oxidation of ammonia with \( \text{O}_2 \) was simulated using COMSOL Multiphysics showing the three products \( \text{N}_2 \), \( \text{N}_2\text{O} \), and NO appearing at increasing temperatures. All reactions were of the first order in the concentration of \( \text{NH}_3 \). Apparent data show strong effects of the deactivation on the kinetics. The apparent activation energies decrease when the catalyst gets deactivated. The effects of the rate of formation of \( \text{N}_2 \) by poisoning is minimal if any. Both the formation of \( \text{N}_2\text{O} \) and NO show decreased activation energies when the catalysts are deactivated. Their pre-exponential factors decrease considerably too. All products of the oxidation of \( \text{NH}_3 \) with \( \text{O}_2 \) could be nicely represented in the simulation when the concentrations of \( \text{N}_2 \), \( \text{N}_2\text{O} \), and NO were fitted. The concentrations of \( \text{NH}_3 \) and \( \text{H}_2\text{O} \) obtained by a mass balance in the simulation were not close to experimental values.

ACKNOWLEDGEMENTS

The author wishes to thank Mr Martin Brunzt, who performed the reaction experiments. A Swedish diesel engine test company is acknowledged for supplying the fresh and deactivated catalyst samples as well as the testing unit. This simulation study did not receive any specific grants from funding agencies in the public, commercial, or not-for-profit sectors.
