**ABSTRACT**

We present the first far-IR observations of the solar-type stars \( \delta \) Pav, HR 8501, 51 Peg and \( \zeta^2 \) Ret, taken within the context of the DUNES Herschel Open Time Key Programme (OTKP). This project uses the PACS and SPIRE instruments with the objective of studying infrared excesses due to exo-Kuiper belts around nearby solar-type stars. The observed 100 \( \mu \)m fluxes from \( \delta \) Pav, HR 8501, and 51 Peg agree with the predicted photospheric fluxes, excluding debris disks brighter than \( L_{\text{dust}}/L_\star \sim 5 \times 10^{-7} \) (1 or several) around those stars. A flattened, disk-like structure with a semi-major axis of \( 100 \) AU in size is detected around \( \zeta^2 \) Ret. The resolved structure suggests the presence of an eccentric dust ring, which we interpret as an exo-Kuiper belt with \( L_{\text{dust}}/L_\star \sim 10^{-3} \).

**1. Introduction**

The discovery of infrared excess emission produced by cold, optically thin disks composed of micron-sized dust grains around main sequence stars is one of the main contributions of IRAS (Aumann et al. 1982). Since the lifetime of such grains, set by delective destructions, Poynting-Robertson drag and radiation pressure, is much shorter than the ages of these stars, one must conclude that those dust disks - called debris disks - are continuously replenished by collisions of large rocky bodies (Backman & Paresce 1993). Observations of debris disks provide powerful diagnostics from which to learn about the dust content, its properties and its spatial distribution; in addition, since dust sensitively responds to the gravity of planets, it can be used as a tracer of the presence of planets. Thus, observations of debris disks around stars of different masses and ages inform us about the formation and evolution of planetary systems, since they are a direct proof for the existence of planetesimals and an indirect tracer of the presence of planets around stars.

In the Solar System, the asteroid and Kuiper belts are examples of debris systems; in particular, the Kuiper belt has an estimated dust luminosity \( L_{\text{dust}}/L_\star \sim 10^{-7} \sim 10^{-6} \) (Stern 1996). IRAS was only able to detect bright disks, \( L_{\text{dust}}/L_\star > 10^{-5} \), mainly around A and F stars; ISO extended our knowledge to a wider spectral type range and found a general decline with the stellar age (Habing et al. 2001, Decin et al. 2003). A remarkable step forward has been achieved by Spitzer, studying debris disks as faint as \( L_{\text{dust}}/L_\star \) several times \( 10^{-6} \), their incidence from A to M type stars, the age distribution, the presence of planets, etc. (e.g. Su et al. 2006, Trilling et al. 2008, Bryden et al. 2009). Spitzer has, however, several limitations. Its poor spatial resolution prevents us from constraining fundamental disk parameters which require resolved imaging, and the confusion limit inherent in its large beam limits its detection capability to cold disks brighter than the Kuiper belt by around two orders of magnitude. Also, Spitzer is not sensitive longward of 70 \( \mu \)m, wavelengths particularly important for the cold disks generally found around Sun-like stars. The far-infrared 3.5 m diameter Herschel space telescope (Pilbratt et al. 2010) with its instruments PACS (Poglitsch et al. 2010) and SPIRE (Griffin et al. 2010) overcomes these limitations, offering the possibility of characterising cold, \( \sim 30 \) K, debris disks as faint as \( L_{\text{dust}}/L_\star \) few times \( 10^{-7} \) with spatial resolution ~ 30 AU at 10 pc, i.e., true extra-solar Kuiper belts.

DUNES is a Herschel OTKP designed to detect and characterise cold, faint, debris disks, i.e., extra-solar analogues to the Kuiper belt, around a statistically significant sample of main-sequence FGK nearby stars, taking advantage of the unique capabilities of Herschel with PACS and SPIRE. The data will be analysed with radiative, collisional and dynamical dust disk models. A complete description of DUNES goals, target selection, and stellar properties will be presented elsewhere (Eiroa et al. 2010, in preparation). The objectives of the DUNES survey are complementary to those of the OTKP DEBRIS (Matthews et

Table 2 gives J2000.0 equatorial coordinates of δ Pav, HR 8501, and 51 Peg at 100 μm, as well as their optical positions. PACS positions are corrected from the proper motions of the stars. Differences between the optical and 100 μm positions are within the uncertainties for Herschel pointing. Of the three stars, only δ Pav has been detected at 160 μm.

100 μm FWHM values of δ Pav have been estimated using a 2-D gaussian fit. This procedure did not produce reasonable results for HR 8501, perhaps due to the faintness of the star; in this case the FWHM has been estimated from intensity profiles along the R.A. and Dec. directions. For 51 Peg, observed in PS mode, the FWHM estimate is also based on some additional point-like sources visible in the PACS field. The 100 μm FWHM estimates are given in Table 2. The 160 μm 2-D gaussian fit for δ Pav gives FWHM = 11°×8.9°, with conservative errors ~ 1°. These values and the elongated beam are consistent with the expected results for point sources (see the technical notes PICC-ME-TN-035/036 in http://herschel.esac.esa.int/AOTsReleaseStatus.shtml).

Aperture photometry has been used to estimate the flux of the stars. Table 2 gives fluxes and errors taking into account the correction factors indicated in the aforementioned technical notes. The sky noise was 2.5×10⁻5 Jy/pixel and 2.7×10⁻5 Jy/pixel for the 160 μm SM data of δ Pav and HR 8501, respectively. The sky noise is considerably higher in the PS-mode 51 Peg image (=4.3×10⁻5 Jy/arcsec²) due to the very irregular background and presence of negative signals. The 160 μm sky noise was 4.9×10⁻5 Jy/pixel for the δ Pav data. The absolute calibration uncertainties are 10% in the blue and green bands and better than 20% in the red band.

3.2. ² Ret (HIP 15371)

Fig 1 shows the SM PACS images of ² Ret. An East-West oriented structure is seen at 70 and 100 μm. It consists of two point-like flux peaks embedded in a faint, extended emission, which displays a secondary diffuse maximum at its Western side. Both point-like peaks have similar brightness in the green band, but the Eastern point-like peak is much fainter in the blue band. The two point-like sources are unresolved in the lower-resolution 160 μm image; instead a single bright peak is observed at that position with a secondary maximum at the position of the 70/100 μm Western diffuse emission.

Table 3 gives positions at 70 and 100 μm of both point-like sources, and of the brightest 160 μm peak; the optical position of ² Ret is also given for comparison. The brightest 70 μm peak coincides with the optical position of the star within the Herschel pointing error; this result and the fact that its PACS 70 and 100 μm fluxes are similar to the expected ² Ret photopheric fluxes (see below) lead us to identify this point-like PACS object with the optical star. There is a small shift between the 70 and 100 μm positions of ² Ret, but we note that a similar shift is found for other field objects - a blue object very close to the ² Ret complex towards the South-West; and two red objects, one towards the North-West and one towards the Northeast (see Fig. 1).

The middle panels of Fig. 1 show isocontours plots. The optical position of ² Ret is marked. 100 μm and 160 μm contours have been spatially shifted so that the peak positions of the mentioned field objects coincide in all three bands (those objects are not shown in the isocontour plots). The size of the whole structure changes with wavelength from ≈ 25° × 15° in the blue to ≈ 40° × 15° in the red band. East-West intensity profiles are shown in the bottom of Fig. 1, together with similar profiles of α Bootis. The blue and green intensity profiles show the point-like character of ² Ret, as well as of the faint peak at the East, called PS-E hereafter; the profile in the red band also shows point-like behaviour for the brightest 160 μm peak, ² Ret+PS-E in Fig. 1 and Table 3. The Western diffuse peak (“W” in Fig. 1) appears very prominent in the green and red profiles, while it is very faint compared to ² Ret in the blue profile. North-South profiles (not...
Table 2. Equatorial coordinates, FWHM at 100 µm, observed fluxes with 1σ statistical errors ($F_{\text{PACS}}$), and predicted photospheric fluxes ($F_\star$). Absolute PACS uncertainties are ~10% and less than 20% for 100 and 160 µm, respectively. Flux units are mJy.

| Star   | Optical position (J2000) | PACS 100 µm position (J2000) | PACS 100 µm FWHM | $F_{\text{PACS}}$ | $F_\star$ | PACS 160 µm |

Fig. 1. PACS results of ζ² Ret. Panels from left to right: 70 µm, 100 µm, and 160 µm. Upper panel: Field size is 100′′×100′′ with East to the left and North up. Middle panels plot isocontours. Note that the field size is different from that displayed in the upper panels. The “star” symbol, position (0,0), corresponds to the optical star (Table 3). A segment indicating 120 AU is shown. Contours: 70 µm: 3,4,6,9,12,15,24σ, 100 µm: 3,4,5,6,12,14σ, 160 µm: 3,6,9,12,15,18σ (1σ values are indicated in the text). Lower panels: R.A. intensity profiles through the peak flux of ζ² Ret (solid line). For comparison, R.A. intensity profiles of the calibration star α Bootis are also plotted (dashed lines), scaled to the peak flux of ζ² Ret (70 and 100 µm) and ζ² Ret+PS-E (160 µm). The α Bootis profile is also scaled and superimposed to PS-E in the 100 µm panel.

shown) do not resolved either ζ² Ret, PS-E, or ζ² Ret+PS-E in any band, i.e. they are point-like along that direction with no hint of any faint extended emission.

Table 3 gives PACS fluxes estimated using the flux peaks of the point-like sources and integrating over beam sizes given by $\pi (\text{FWHM}_x \times \text{FWHM}_y) / 4 \ln 2$. The PACS source identified with ζ² Ret is a blue object, while PS-E is a red one. The flux at 160 µm corresponds to ζ² Ret+PS-E, but PS-E is the main contributor to the flux at this wavelength - the emission is peaking more towards PS-E (Fig. 1). The total flux of the ζ² Ret complex is 44.5 mJy, 40.4 mJy, and 42.6 mJy in the blue, green and red bands, respectively. The estimated 70 µm flux for the whole complex agrees very well with the unresolved Spitzer flux of 46 mJy at the same wavelength (Trilling et al. 2008).

4. Discussion

Our data do not reveal any cold dust disk around δ Pav, HR 8501 or 51 Peg, since the observed and predicted 100 µm photospheric fluxes coincide within the uncertainties (Table 2). Assuming dust temperatures of 40 K (peak blackbody fluxes at ~100 µm), we can exclude debris disks with $L_{\text{dust}} / L_\star \geq 5 \times 10^{-7}$ (1σ) (Eqn. 4 from Beichmann et al. 2006).

ζ² Ret, located at 12 pc, is a G1 V star with a bolometric luminosity of 0.97 $L_\odot$ and an estimated age of ~2-3 Gyr (Eiroa...
The fluxes are indicated by black symbols. Blue triangles are "Ret" point-like sources; red crosses are PS-E; green triangles are squares are total fluxes from the photospheric fit (T which are mean values found using the DUNES discovery tool, et al. 2010, in prep.). Figure 2 shows the stellar SED as well as flux from PS-E is also plotted with a red cross (see text).

The agreement between the observed 70 and 100 µm fluxes from PS-E and the whole complex; a PHOENIX stellar photosphere (Brott & Hauschildt 2005) is also plotted. The blue bright point-source and those predicted by the photospheric fit, 24.7 mJy and 12.1 mJy at 70 and 100 µm, respectively, is excellent. This photometry and its positional alignment with the stellar position support our claim that the PACS blue emission of "Ret" is L_{dust}/L_{*} ≈ 10^{-3}.

We have the interesting scenario of a G1 V star surrounded by optically-thin 30-40 K emission. This is the temperature range expected for black body dust grains orbiting at distances ~100 AU from the star. This is consistent with the projected linear distances from "Ret" to PS-E and to the Western diffuse emission of ~70 AU and ~120 AU, respectively. The red image suggests a flattened, disk-like structure with the star located asymmetrically along the major axis, while the blue and green images suggest it is ring-like given the flux cavity towards the West from the star. We interpret the structure in the PACS images as a dust ring surrounding "Ret". We attribute the observed East-West asymmetry to a significant disk eccentricity - e ≈ 0.3. Similarly, an offset is observed in the Fomalhaut debris disk with e = 0.1 (Stapelfeldt et al. 2004). Maintaining a stable eccentric ring requires an external driving force such as a shepherding planet (Wyatt et al. 1999) and in the case of Fomalhaut the predicted planet has been been directly imaged (Kalas et al. 2008). The disk asymmetry in the "Ret" system may likewise be the signature of an unseen planetary companion. While this is an exciting possibility, other forces might also produce disk asymmetry. For example, interaction with the ISM is probably responsible for the strong asymmetry observed around HD 61005, since its brightness offset is well aligned with the star’s space motion (Hines et al. 2007). A more profound analysis and detailed modeling of "Ret" and its Kuiper belt is deferred to a future paper.

5. Conclusions

Our results show the capability of Herschel/PACS to detect and resolve cold dust disks with a luminosity close to the solar Kuiper belt, which will allow us to deepen our understanding of planetary systems, in particular those associated with mature stars. Specifically, our data exclude the existence of cold debris disks with L_{dust}/L_{*} ≳ 5 × 10^{-3} (1σ) around the solar-type stars δ Pav, HR 8501 and 51 Peg. On the other hand, the data show that "Ret" is a good example where cold disks around nearby stars, very much unlike the solar Kuiper belt, can be resolved and studied in great detail with the Herschel space observatory.
